

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

### THE TREATMENT OF OBSTINATE DROPSIES.\*

BY JAMES TYSON, M.D.,

Professor of Clinical Medicine in the University of Pennsylvania.

Between a blind confidence in drugs which makes a fair estimate of therapeutics impossible, and an equally blind skepticism which nullifies therapeutics altogether, lies a golden mean of rational treatment the results of which are at once an encouragement to the

practising physician and a stimulus to further effort to extend the usefulness of our art. I shall attempt to substantiate this proposition by illustrations drawn from my experience in the treatment of obstinate dropsies. This subject is selected not simply because of my experience with it, but also because it is a condition uninfluenced by mental impressions, a condition which never passes away of itself, going on from bad to worse if left alone, and a condition which unfortunately too often resists treatment altogether. The cases on which my remarks are based fairly represent each of the three great etiological categories of heart disease, kidney disease, and liver disease. Contrary to what would

\*Read before the Blair County Medical Society, at Altoona, Pa., Oct. 19, 1897.

be supposed, experience shows that the difference demanded in the treatment of these three groups of cases is not usually very great, such difference being required rather by peculiarities in the individual case than by etiological conditions. This must be my apology for elevating for the time being what I truly recognize as a symptom to the dignity of a disease.

Previous to entering upon the subject proposed, let us see in what it really consists. Our patient has general anasarca, his tissues are distended with serum—waterlogged, as it were; there is effusion into one or both pleural sacs and probably into the peritoneal cavity. Many pounds of water are thus stored away which hamper his movements, interfere with important functions, gradually reduce his strength, and ultimately take away his life. Our task is to get rid of this dangerous accumulation. The difficulty is increased by the fact that he is necessarily ingesting water, not only in the shape of liquids but in the solid food, which is at least three-fourths water. It is plain, therefore, that we must get more water out of him than we put into him. It is evidently impossible to reduce a dropsy in a patient who is passing, say, thirty-two ounces of water in the shape of urine and other secretions while he is ingesting three and four times as much in the shape of food and drink.

There are two ways, therefore, in which our object may be accomplished: first, by cutting down the liquid ingested, and second, by increasing the output of liquids. The first of these has heretofore received less consideration than the second, in fact has been too often ignored. Nay more, by the ingestion of large quantities of water for its supposed diuretic action the very opposite effect is sometimes produced. Water is added to the tissues rather than removed from them. On the other hand, in a large number of cases we have taken a decided step towards the attainment of our object when we limit the ingestion of liquids or reduce them to a minimum.

The latter may be accomplished, as suggested by Matthew Hay, by reducing to a minimum the amount of liquid ingested, while permitting an ordinary mixed diet of easily assimilable food; or more satisfactorily by placing the patient on a diet of milk or dilute milk limited in quantity. The latter method is more satisfactory, probably because commonly no food is so easily assimilated as milk and partly because the quantity ingested is

easily estimated. I usually begin with so small a quantity as two to four ounces every two hours, keeping this up until the patient complains of hunger. Indeed, the dropsy often does not begin to disappear until the patient begins to complain of hunger. It would seem as though under these circumstances the interstitial effusion is being used up as food. After a decided effect is produced on the anasarca, or it has entirely disappeared, the quantity of milk is grudgingly increased. Then gradually other articles of food are added until the patient's appetite is satisfied.

Another very important advantage in a restricted diet is that it favors the attainment of the second part of the treatment, viz., the withdrawal of superfluous liquids from the body. I have observed over and over again that patients who are eating freely do not respond to diuretics and other remedies intended to secure this object so long as this large feeding is kept up. Such restriction of food may be distasteful to the patient, but he is usually willing to adhere to it if the rationale of its operation be explained, and especially if favorable results are early manifest.

A further indispensable condition of the successful attainment of the second division of our treatment is absolute rest in bed. This is often more difficult to accomplish because our patient has found the upright posture more comfortable, breathing more freely. The advantages of rest are most strikingly shown in hospital patients, where in cardiac and renal cases at least rest alone will sometimes entirely remove a dropsy. The reason is easy to see. The output of muscular energy in an ordinary day's work of eight hours is variously estimated by different physiologists at from 150,000 to 316,800 kilogrammeters, while the ordinary work of the heart equals 75,000 to 86,970 kilogrammeters. In hard bodily labor the total output of muscular energy is increased to from 220,000 to 400,000 kilogrammeters. Now when the patient is put to bed all this extra work is saved to the heart. In the case of professional men and others who do less muscular work the saving is not so great, but it is still considerable, and it is true of mental as well as physical work. Rest, mental and physical, then, is a most important agent in accomplishing our purpose.

Rest and regulated diet being secured, we are now ready to avail ourselves of measures calculated to increase the output of fluids from the body by the natural channels,

mainly the kidneys, the bowels, and the skin. The kidney and bowels should invariably be acted on at the same time, or rather the bowels should be first started. It is a waste of time and good medicine to attempt to secure the effect of diuretics without the preliminary action of a purgative. Of purgatives the best for the purpose are usually the salines. Rochelle salt I use more frequently than any other, giving half ounce to an ounce half an hour before food, preferably before breakfast. The Epsom salt is probably more efficient in the same dose, but less palatable. The compound jalap powder should not be forgotten in this connection. It is an admirable aperient in one or two drachm doses. A full dose of calomel, say seven and a half to ten grains, with an equal quantity of sodium carbonate, may be substituted, or blue mass; but the mercurials are much slower in action than the salines, requiring usually several hours, hence they are most conveniently administered in the evening, followed by a saline in the morning. In cases of hepatic disease with ascites these remedies are useful adjuvants. It is of great practical importance to give the saline in as small a quantity of water as possible, preferably not more than four ounces. This accelerates and increases the exosmotic effect by which the blood-vessels are depleted into the alimentary canal. Other purgatives may be demanded by circumstances, but usually those named are the most satisfactory. Epsom salt may be given quite effectually by rectum if any reason exists against its administration by the mouth, as follows: Sulphate of magnesia two ounces, boiling water three fluid-ounces, and glycerin one fluidounce.

Having secured a free action of the bowels, with the patient at rest on a restricted diet, we may select a diuretic. No question of general therapeutics is more unanimously answered than that digitalis is the best diuretic available. It remains to consider briefly which is the best preparation and the best mode of its exhibition. All things considered, the tincture is the most suitable, partly on account of its convenience, but chiefly, if the most modern studies are to be accepted, because alcohol extracts more of the most active and at the same time harmless constituents of digitalis than does water, which is mainly used in making the infusion.\*

\* Modern studies find in digitalis four active constituents, the digitalin of Schmiedeberg, digitoxin, digitalein, and digitonin. Of these, the first three increase the force of the heart's contraction, while digitalin further adds to the rise of blood-pressure by stimulating the vagus nerves

Clinically, however, it is sometimes of advantage to substitute the infusion for the tincture, which should be given in half-ounce doses to adults. From the fact that in making the fluid extract both alcohol and water are used, this preparation may be expected to be an efficient one, but I have not had much experience with it. As to the best method of exhibition, digitalis is one of the drugs which is slow of absorption and slow of elimination. It is, therefore, better administered in full doses at longer intervals than in small doses at closer intervals. I commonly begin with the tincture in ten-minim or twenty-drop doses four times a day, or fifteen minims or thirty drops three times a day. Almost always forty-eight hours supervene before any effect is noted, and we should wait at least this long before concluding upon its action. At the end of this time, if no diuretic effect is produced the dose may be increased to a drachm in the twenty-four hours, which I do not commonly exceed, preferring to change the preparation. The effect is recognized also by a slowing of the pulse, and should this fall to sixty the drug should be discontinued, even though no diuretic action is produced. An irregularity in a pulse formerly regular is also an indication that the drug should be discontinued. On the other hand, it is well known that too much digitalis makes an irregular pulse regular, and there is sometimes considerable difficulty in deciding which of these two conditions operates. The only way to settle it is to discontinue the drug for a full week in order that it may be thoroughly eliminated. Theoretically, at least, nitroglycerin is advantageously associated with digitalis because of its dilating effect on the arterioles, and practically it is without disadvantage. It is a drug of prompt action and short duration. It is therefore rationally given at short intervals, as  $\frac{1}{10}$  to  $\frac{1}{8}$  grain every two hours.

Notwithstanding its efficiency we would be but poorly armed if we had no other diuretic than digitalis. Furthermore, digitalis is a

centrally and peripherally. Digitonin, on the other hand, depresses the vagus nerve peripherally and centrally and depresses the heart muscle. It, therefore, antagonizes the effect of the other three active principles. Now, digitalin and digitalein are easily soluble in alcohol, digitoxin slightly so, and slightly in water. Digitonin and digitalein are soluble in water, but sparingly only in alcohol. It is evident, therefore, why the tincture should be a more active preparation than the infusion. It is true that there is tonic property in the infusion also, because the digitalein contained in it, together with the smaller quantities of digitalin and digitoxin, overbalance the effect of the digitonin.

drug which must be intermitted to secure its efficient action as well as to avert its toxic effect. The drug which is best substituted for digitalis varies somewhat with the nature of the disease causing the dropsy. In cases of *cardiac* disease I at present prefer theobromine. This preference has grown out of a large experience with this diuretic during the past year. In the course of such experience I have found it at times superior to digitalis—that is, it would act when digitalis did not. The dose I have found most satisfactory is forty-five grains in the twenty-four hours, conveniently divided into doses of seven and a half grains every three hours, which allowing for necessary interruptions results in the administration of at least forty-five grains in this period. This dosage is kept up for six days, at the end of which time, if diuresis has resulted, the effect will begin to wear off. During the last day of its administration I usually associate digitalis, continuing this drug after the theobromine is discontinued. In this way the diuretic effect is often kept up some time longer. In two of the cases which I shall report the effect was marvelous, raising the urine to 119 ounces in the twenty-four hours.

Theobromine is regarded as a renal diuretic—that is, as producing its effect by stimulating the action of the renal cells rather than by increasing blood-pressure by strengthening the heart muscle. It is obtained from cacao, and is chemically closely allied to caffeine—caffeine being trimethyl-xanthin, while theobromine is dimethyl-xanthin. It is a substance difficult of solution, but is more soluble in hot fluids than in cold, and is therefore conveniently administered in hot milk. It is also readily soluble in the saliva, and though bitter to the taste it is not unpleasantly so, and may be taken dry on the tongue followed by a mouthful of water. Theobromine is a constituent of diuretin, which is said to be composed of equal molecules of salicylate of sodium and a compound of theobromine and soda, and to contain fifty per cent. of theobromine. Diuretin was introduced several years ago and vaunted as a powerful diuretic suitable in all cases of dropsy, especially those due to chronic Bright's disease, but also in ascites and dropsy due to heart disease. It was claimed to be much superior to theobromine on account of its greater solubility, and was recommended in fifteen-grain doses to the daily quantity of 90 to 105 grains. It failed, however, to secure a footing in this country.

My own experience was that beyond a transient effect rarely lasting longer than the first day it was useless. It is somewhat singular that this more soluble preparation should be comparatively inert as contrasted with the insoluble theobromine, yet this is the conclusion to which I am forced from my own experience, viz., that diuretin is a comparatively worthless preparation while theobromine is a very efficient one. I must also admit that the drug is by no means equally efficient even in cases presenting apparently the same conditions. Different preparations may also vary in quality. I commonly order Merck's.

In this connection I will say what I have to say of a drug already mentioned as closely allied to theobromine, viz., caffeine. A few years ago I used caffeine a good deal as a diuretic, and good results seemed to follow its use, especially in connection with a restricted milk diet. Lately, however, my results have not been nearly so satisfactory, and I use it comparatively rarely to-day for its diuretic action. There is reason to believe that good results follow its prolonged use in cardiac cases in doses of from three to five grains three times a day.

Next after theobromine—indeed, often before it, especially in *renal* disease—comes another drug which I am sure is not sufficiently appreciated. I allude to sparteine sulphate, the active principle of broom. Few who have had much experience in the treatment of dropsy have failed to have their attention called to broom tea. Those who have tried it I am sure have sometimes found it quite an efficient diuretic. It is, however, a nauseous preparation, and the dose is unpleasantly large. Sparteine appears to be its true active principle and is a good diuretic. Heretofore it has been given in too small doses. The dose should never be less than one-fourth grain to adults to the amount of two grains in the twenty-four hours. It may even be increased to three and four grains in this period. I have never exceeded the latter quantity, desisting from its use when no diuresis follows such doses. Yet I am not aware that it is harmful in any dose.

Doubtless some one has ere this wondered why no mention has been made of strophanthus. It is a remedy which has met with favor, but I confess to having been myself greatly disappointed in it. Any results I have secured have been with doses as large as those of digitalis.

I never feel that I have done my duty

towards a case of obstinate dropsy where other measures have failed until I have tried the time-honored combination of calomel, squill, and digitalis. Occasionally I have seen the most marvelous effects from this combination, more particularly in cases of cardiac dropsy, when given in doses of calomel one-half grain, digitalis one grain, and squill one grain, every three hours until diuresis, free purgation, or both, have been obtained. I have seen dropsies disappear completely while using this combination and the patient resume active business life for a time longer. Calomel alone I have found at best a doubtful diuretic, and the fact that it has of late fallen almost entirely into disuse for this purpose seems to justify this conclusion. The small fractional doses often prescribed, such as one-twelfth, one-tenth, one-eighth, one-sixth of a grain, are too slow of effect. I should advise rather at least half a grain with twice as much sodium bicarbonate every hour, or three grains every three hours. From the larger dose a purgative effect at least is soon attained, and if this be associated with a diuretic action it is all the better.

Action on the bowels has been mentioned as an important adjuvant to action on the kidney by diuretics. But purgatives are useful also for their direct effect, the withdrawal of water from the system. To this end the hydragogues which produce watery movements are preferred, including the salines and elaterium. The former are best given in the morning before taking food. Elaterium when it acts nicely is an efficient agent for the withdrawal of water, but it is irregular and uncertain and often causes unpleasant nausea and vomiting. My plan is to give one-sixth to one-fourth of a grain every three hours until an effect is produced. Often there is no response until a number of doses have been given, when suddenly an almost uncontrollable flow of water follows. Once every other day is as often as this drug should be used.

The skin has been alluded to as one of the natural channels availed of to secure elimination of water. It is not usually as satisfactory as the kidneys or bowels because of the unpleasant effect of copious diaphoresis on the patient, the chief symptom complained of being a profound weakness. Why such a debilitating effect should follow a discharge of water by the skin is not plain to me. Sometimes, doubtless, it is exaggerated by the patient. Sweating is induced by the application of dry or moist heat constituting the hot

air and vapor baths, the hot wet pack, and Simpson's bottle-bath. The usual methods of applying the first two are so well known that I will not here give a description of them. On the whole the vapor bath, as constricted with the hot-air bath, will, I think, be found more satisfactory, being less uncomfortable, less likely to produce headache, and more active. The unpleasant sensation often felt in the head may be averted by tying a handkerchief wet with cold water tightly around the forehead. The effect of the Turkish bath, which is less objected to by the patient, is similar. The hot wet pack and the bottle-bath, or Simpson's bath, are very pleasant forms of baths. In the former the patient is wrapped in sheets wrung out in hot water and finally covered with blankets. In the Simpson bath he is surrounded with hot-water bottles, wrapped with towels wrung out in hot water, and finally covered with blankets. The sweat thus produced is less trying and the patient often takes a refreshing sleep during it. The results of these methods of elimination are best maintained by keeping the patient in bed after the bath, and are best employed in acute cases and for uremia.

One drug only is markedly efficient to produce skin action, viz., jaborandi or its active principle pilocarpine. The latter is the most convenient preparation, and the best method of administering it is by the hypodermic syringe. One-fourth of a grain should be the maximum dose, and a powerful effect may be produced if it is associated with artificial warmth. The patient should also be clad in a sweater or lie naked between blankets rather than in a muslin shirt or between muslin sheets. Should dangerous edema of the lungs arise it may easily be controlled by a hypodermic injection of  $\frac{1}{16}$  or  $\frac{1}{8}$  of a grain of atropine.

Similar to the action of cardiac tonics and destined to be a valuable auxiliary in the treatment of dropsies, especially where the heart is at fault, is the Schott or Nauheim treatment by baths and exercises. The treatment is so called from the brothers Schott, more or less identified with it, and from the village of Nauheim near Frankfurt-on-the-Main, where water charged with carbonic acid and containing certain saline constituents, mainly sodium chloride and calcium chloride, flows abundantly from natural springs, warmed by nature's furnaces. Fortunately the baths can be carried on at home with almost the same results as at Nauheim, else it would scarcely be worth while to con-

sider them, as comparatively few invalids can afford to go to distant Nauheim, though marvelous results are said to attend such visits. The water of Nauheim has a temperature of 81° F. to 92° F. The bath of higher temperature is employed first, the duration being eight minutes. With successive baths the temperature is gradually reduced to 83°, while the duration is prolonged to fifteen minutes, with an intermission at the end of three or four days. As the temperature is reduced the saline constituents are gradually increased by the addition of the "mutter-lauge" or "mother lye" obtained by evaporating the natural spring water. A course consists of twenty to twenty-five baths. Towards the end comes the "sprudel" bath, the water of which is highly charged with carbonic acid, and the "sprudel strom" bath in rapidly moving water similarly charged. The little bubbles of carbonic acid stick closely to the skin, giving the patient a delightful sensation of warmth which takes away any unpleasantness which might arise from the water at this temperature. After the bath the patient is carefully dried with warm towels, some light refreshment is taken, and he rests for an hour.

The baths are imitated at home by dissolving chloride of sodium and chloride of calcium in water to which carbonic acid is added by decomposing bicarbonate of potassium by hydrochloric acid. Dr. C. N. B. Camac has calculated the required quantities of salt to each forty gallons of water for six different strengths of baths. In the baths I recommend I have adopted the proportions of sodium chloride and calcium chloride calculated by Camac, but have slightly modified the proportions of carbonic acid-forming constituents, making three strengths of the latter after the method recommended by Bezley Thorne, of London.

Bath No. 1: Sodium chloride, 4 pounds; calcium chloride, 6 ounces.

Bath No. 2: Sodium chloride, 5 pounds; calcium chloride, 8 ounces.

Bath No. 3: Sodium chloride, 6 pounds; calcium chloride, 10 ounces.

Bath No. 4: Sodium chloride, 7 pounds; calcium chloride, 10 ounces; sodium bicarbonate,  $\frac{1}{4}$  pound; HCl (25 per cent.), 12 ounces.

Bath No. 5: Sodium chloride, 9 pounds; calcium chloride, 11 ounces; sodium bicarbonate, 1 pound; HCl,  $1\frac{1}{4}$  pounds.

Bath No. 6: Sodium chloride, 11 pounds; calcium chloride, 12 ounces; sodium bicarbonate, 2 pounds; HCl, 3 pounds.

The alkali should always be slightly in excess unless a porcelain or paper tub is used.

In preparing the bath the salts, including the right proportion of bicarbonate of sodium, are dissolved in the water. The bottle containing the hydrochloric acid is inverted and lowered until its mouth is below the surface, when the stopper is withdrawn and the bottle moved about so as to diffuse the acid as uniformly as possible through the water. In this way the bath is made ready in a few minutes. The carbonic acid is the most unsatisfactory feature of the artificial bath, since it is rapidly dissipated and produces only feebly the effect of the acid in the natural baths. Hence the patient should be promptly put into the bath after the HCl is added, lest the  $\text{CO}_2$  is lost before he can get the effect of it. My plan has been to give the baths on alternate days, using the weaker until its effects are exhausted, then passing on to Nos. 3 and 4 in the same manner. Nos. 5 and 6 are not often called for.\*

As already stated, the baths are most efficient in cardiac disease, but they are also useful in renal affections. Their immediate effect is a diminished pulse-rate, intensified heart sounds, diminished breathing-rate, while the dilated heart is reduced in size—under favorable circumstances to almost its natural limits. The effect is also to increase the action of the kidneys and that of the skin. These effects are ascribed to the carbonic acid, the chloride of sodium, and chloride of calcium. In three or four days, it is said, they are apparent in a free flow of urine, which may continue for days and weeks; metabolic changes are accelerated and improved; the deep seated organs, especially the liver and pelvic viscera, are relieved of congestion; while the heart, relieved of its burden, and contracting on its contents fully and without perturbation, derives from its improved coronary circulation material for the repair of its weakened or damaged tissue. In a word, the effects of these baths are said by those who have watched them to be marvelous and incredible to any one who has not observed them. While I have not yet seen the marvelous effects thus described, I have seen very decided improvement attend their use.

As to *rationale*, it is thought stimulation is exerted through the centripetal nerves on the cardiac and vasomotor centers, improving the nutrition of the heart, and indeed of the

---

\*While reading the proof of this article I am having constructed for use at the Hospital of the University of Pennsylvania an apparatus for introducing carbonic acid into the water of the bath after a device suggested by Mr. Smitheman, a student of medicine.

whole body. It is supposed by Schott that this effect is increased by the imbibition of a small amount of salts into the superficial layers of the skin, by which a more prolonged stimulation is kept up. A slight sense of oppression to breathing is sometimes present in the course of the first two or three baths, which should not alarm the patient. It is described by Dr. Richard Greene, of London, who was himself treated at Nauheim, as a sensation of "girdling" by hoops applied to the thorax.

A part of the Nauheim treatment are the resistance exercises or "Widerstandgymnastik" suggested by Ling, but especially utilized and further developed by the brothers Schott at Nauheim. The elder, August Schott, died in 1882, but the younger, Theodor, continues the leading physician at Nauheim. The exercises are not as easily described as shown by actual practise, but briefly they may be said to include every reasonable movement of the arms and legs, gently resisted by opposite pressure exerted by the physician or attendant. Thus, there is flexion of the arms on the forearm, carrying the arms forward until the palms are apposed, then backward from this position until they are in a line, and raising from the sides upwards until they touch the sides of the head. There are also radial movements of the arms alongside of the head, etc.—in all nineteen movements. Similar movements are made with the legs, including flexion and extension at the knee, ankle, and hip-joints. They include also lateral and twisting movements of the trunk.

The exercises are not commenced until some very positive effect of the baths is secured, when they are associated with the baths or substituted after the latter are discontinued. The effects of these gymnastics are described as identical with those of the baths. The extremities become warm, the breathing is deepened, the sense of oppression is relieved, the pulse becomes slower, the dilated heart area reduced. Even the liver, which is so often enlarged in heart disease as a result of passive congestion, is said to be reduced in size.

In carrying out the gymnastics it is all-important that the patient should not be fatigued; the movements should be made slowly, and the rule of action should be moderate exertion and no fatigue. No movement is to be repeated twice in succession, and each single or combined movement is followed by an interval of rest. The patient should be carefully watched, and the least

suggestion of cyanosis or shortness of breath should be a signal for discontinuing the treatment. The movements have, therefore, a more limited application than the baths, since a condition of their success is the absence of any consequential embarrassment of the circulation or breathing. Rarely, however, they may precede the baths with advantage, as where the patient is too ill to be removed from bed, when their cautious use may be practised until strength is attained to allow the baths to be used at a later date.

In my own practise I have associated massage with this treatment with the most satisfactory results. The massage may even be performed while the patient is in the tub, and it serves at least to interest and entertain him. Massage alone is a very valuable adjuvant in the treatment of dropsies. I have seen many a limb swollen and distended to almost stone-like hardness rendered soft and flaccid by a half-hour's massage, which seems to produce some absorption of the effused liquid.

There are cases in which all the resources described fail of their purpose, and liquid remains stored away in the interstices of the body and in the serous cavities. The latter may require to be relieved by paracentesis of the chest and abdomen, and the former by punctures made with the needle, and incisions into the limbs or the scrotum, which often becomes enormous. Into these parts Southey's tubes may be inserted and many ounces of liquid thus drained away. These tubes must be carefully watched and kept aseptic as possible, as by neglect of such precautions septic inflammation may be induced. Punctures may be made by the needle or by the scarificator. But these punctures soon become very annoying to the patient and he grows to hate them, and I am inclined to think an incision, say behind the ankle, done under local anesthesia produced by ice and salt or the chloride of ethyl, is to be preferred. Anesthetics should not be omitted as the patient is enough annoyed by his sufferings, and he should not be allowed to suffer more than necessary. Many of you have seen spontaneous rupture of the skin take place and large quantities of water thus drained away. I have not infrequently seen the beginning of improvement date from such rupture, so that I am in the habit of telling the patient that such an event is fortunate.

The following are illustrative cases:

CASE I.—*Hypertrophic cirrhosis, ascites, general anasarca.* This case was one of enlarged liver and spleen with albuminuria in

a man of fifty-three years, who twenty years previously had acquired a chancre which was followed by secondary symptoms of short duration. The lesions were, therefore, presumably syphilitic. The patient had always been a free eater and drinker and a hard worker in law, which was his profession. When he came under my care there was general anasarca; the legs and thighs were distended to bursting; the scrotum was as large as a child's head, excoriated, red, and painful, while it was impossible to keep it free from contact with urine and liquid discharges from the bowels, which caused agonizing irritation every time these evacuations took place. The liver rose high up under the dome of the diaphragm on the right side, reaching to the fourth rib, and extending below the edge of the thorax. There was also effusion into both pleural sacs, and the urine was loaded with albumin. The heart was enlarged, but there was no evident sign of valvular disease. The illness, dating from December, 1894, began with shortness of breath, which gradually grew worse and often amounted to orthopnoea, which I ascribed to encroachment on the breathing space by the hydrothorax and enlarged liver and dilatation of the heart rather than to valvular disease of the latter.

He was admitted to the Hospital of the University of Pennsylvania as a private patient on the 31st of July, 1896. The urine voided in the first twenty-four hours after admission amounted to twenty-six ounces and was dark hued, had a specific gravity of 1030, was copiously albuminous, and contained numerous hyaline and pale granular casts.

The treatment instituted was a half ounce of Rochelle salt each morning before breakfast with tincture of digitalis in ten-minim doses. After two days, the urine remaining uninfluenced, I added sparteine sulphate in one-fourth grain doses every six hours, continuing the digitalis and Rochelle salt, which acted well. At the end of the fourth day the amount of urine recorded was 30 ounces; at the end of another twenty-four hours, 44 ounces; at the end of another, 53 ounces; another, 72½ ounces; and another, 74 ounces. Then it fell to 50, 32½, 37, 30, and 35. At this time the pulse began to be intermittent, and as I believed this intermission was due to the so-called cumulative effect of the digitalis this drug was discontinued. Unfortunately the pulse and temperature chart of this date have been lost, and the rate of the pulse is unknown. During this time his diet was what was called light special, consisting

of bread and butter, a limited amount of milk, chicken, eggs. We kept in view the fact that in order to reduce dropsy more fluid must be excreted than is ingested. With cessation of the effect of the sparteine this drug was also discontinued, and the patient was put on a pure milk and water diet, not exceeding thirty-six ounces in the twenty-four hours, and a silver cannula with rubber tube attached put into the scrotum. The urine voided continued 38, 35, 30 ounces, while to this was added liberal drainage by the tube, 32½, 18½, 17, 6 and 4 ounces being recorded, while there was also much oozing from punctures made in the legs. The swelling gradually declined. After what seemed a sufficient intermission, the digitalis and sparteine were again commenced. No marked effect on the urine followed, the maximum obtained being forty ounces, but the oozing continued liberal. Three or four days later calomel was added in doses of three grains every four hours, eighteen grains being given in the first twenty-four hours and twenty-one in the second without any appreciable effect on the urine, which continued at about twenty-seven to thirty-one ounces.

Theobromine was then substituted for the sparteine, and in a short time the urine again increased 52, 58, 54 ounces. That this effect was due to the theobromine subsequent experience amply proved, for repeated trials with digitalis alone were without effect. Strophanthus was equally inefficient, while theobromine was promptly followed by copious diuresis. Improvement continued until the dropsy almost all disappeared from the thighs and trunk, though considerable remained in the pleural cavities. On the 26th of October the right pleural sac was tapped, 33½ ounces being drawn off. This cavity was tapped again later, as was also the left side. On the 13th of November he had a partial monoplegia of the right arm, which I thought might be due to an embolus or thrombus of the vessel supplying the arm area of the cortex. From this he gradually recovered, and it did not recur.

As in another case to be referred to, as the dropsy of the legs improved effusion into the abdomen increased, and on January 29 eight pints and thirteen ounces were drawn off. The Nauheim baths were started February 5. The fluid again accumulated and was removed by tapping February 25. Remembering the effect of a like experience with him he was placed on a starvation diet of milk and Vichy, of each two ounces every

two hours, while the theobromine was ordered, seven and a half grains every four hours. By February 27 the urine rose to sixty ounces. The Nauheim baths were instituted February 20. By March 5 his breathing-rate, which had been 30 to 37, was reduced to 20, essentially normal.

Time and again in the course of the history of this case the urine was started by theobromine when all else failed, while as often digitalis remained useless. I might state, however, that for a time the use of digitalis by the rectum in drachm doses of the tincture was efficient. Perhaps the effect by the mouth was influenced by the patient's extreme repugnance to it. He constantly recognized it when administered and hated it. As was to be expected in an intractable case theobromine also gradually lost its effect, but by means of it and an occasional tapping we were able to carry him along, and in the latter part of June and early in July he drove out almost daily. He was tapped last on the 6th of July and the fluid kept down for a time by the theobromine, but finally this drug lost its effect altogether. He returned to his home soon after and died suddenly September 3, it being generally conceded kept alive for many months by the treatment.

The autopsy disclosed a huge liver; the spleen was twice the normal size. The kidneys were less altered, the changes being apparently those of passive congestion.

CASE II.—*Mitral incompetency, general anasarca, ascites, hydrothorax.* Mrs. L., aged thirty-six, a native of Ireland, was admitted to the University Hospital January 1, 1897. She was the mother of seven children, and had always been a hard working woman until failing health compelled her to give up work ten months before admission. She had been a sufferer from rheumatism, and ten years ago had a severe attack which confined her to bed three months. Ever since this attack she had been subject to swelling of the feet, especially after standing. About ten months previous to admission, just after the birth of her youngest child, she began to suffer with shortness of breath on exertion, palpitation of the heart, and severe pain between the shoulders. Her feet and legs became edematous, and seven months later her abdomen began to enlarge. Then she was admitted to St. Timothy's Hospital, Roxboro, Pa., where she improved, and after five weeks was discharged much relieved, and was even able to do light work for about a month. Soon, however, her symptoms re-

turned, her urine becoming scanty and high colored, her limbs swollen, her abdomen to fill up. She suffered much from pain in the epigastrium and left hypochondrium.

On admission to hospital the symptoms described were present; even her face was swollen. Besides the ascites, there was some pleural effusion in both sides. There was a loud double mitral murmur and a tricuspid systolic murmur with hypertrophy of left auricle and left and right ventricles. The liver was enlarged, extending below the edge of the ribs, and was everywhere tender. Her urine was albuminous and contained numerous hyaline and pale granular casts. She was intensely anemic, had no appetite, and looked a forlorn, ill woman.

Under rest and digitalis she improved, and at the end of ten days her dropsy had much diminished, but the ascites remained, and on the 16th of January she was tapped from the abdomen. The fluid slowly reaccumulated. On the 22d she received her first Nauheim bath, and was tapped again on January 26. The baths had an invigorating effect and reduced the pulse and breathing-rate, but I cannot be confident that the cardiac boundaries were appreciably altered. The baths were given on alternate days, but were discontinued after four were given. On the 29th she was tapped from the right thorax, thirty-three ounces being drawn off. Digitalis and strophanthus having both been without effect, sparteine was ordered February 2 in one-fourth grain doses every three hours throughout the twenty-four. Later it was associated with digitalis, and though there was some response it was temporary, and the abdomen refilled rapidly. On the 21st of February she was passing only eleven ounces of urine. On that day theobromine was ordered, and in two days the urine voided was 65 ounces, the next day 119 ounces, the next 96, the next 86, the next 58, and the next 57. The secretion then declined, but in the meantime the ascites had disappeared as well as the dropsy from the arms and legs. Her heart being rapid and irregular in its action, digitalis was ordered March 11. It was efficient in regulating the heart, but did not act as a diuretic. By the 15th of March there was again such an accumulation of fluid in the pleural cavity that eight pints were withdrawn by tapping, followed by theobromine with a view to keeping down the accumulation. On the 22d of March she was passing only about seven ounces of urine, and by the 28th she was voiding sixty. By the

4th of April the urine was again scanty and the abdomen filling up. Citrate of potassium having been tried without effect, theobromine was again ordered on the 26th of April, when the urine was but twelve ounces. By the 30th it was seventy-two, and on April 3 it was fifty-two ounces. On April 13 her urine was free from albumen. It is not necessary to read the history further. Thereafter, whenever the ascites appeared theobromine was ordered with the usual effect. She was discharged July 12, of course not cured—she never could be—but so much better that she thought she would like to go home and remain for a while with her children. When last heard from she was living, but not as well as when in the hospital.

My results with theobromine in this case have not been realized with every one. In another patient, a woman about the same age, with identical heart lesions, it was absolutely useless. This woman I have tapped nine times, the last time removing three gallons, yet when not weighted down with water she is active and even much of the time does her own housework. An interesting change of symptoms took place. When I first saw her she was very dropsical in her legs; but when the accumulation occurred in the abdomen, probably due to the contracting liver, the swelling in the legs disappeared and remained absent for a long time. It is just beginning to return.

CASE III.—*Subacute parenchymatous nephritis, anasarca, hydrothorax; recovery.* Mr. A., aged thirty-six, a merchant, was admitted as a private patient to the University Hospital, September 14, 1896. His father died of apoplexy, which may or may not have had to do with renal disease; otherwise his family history was negative. Up to five years ago he had little or no illness. Has since suffered rather freely from gastro-intestinal attacks with vomiting and diarrhea, but otherwise has not been much ill. Three months before admission he had one of these attacks, which the physician called subacute inflammation of the bowels. He was only two days in bed, but since then he has not been well. He tried to return to work, but could not keep at it. About July 15, while at Atlantic City, he noticed that his feet were swelling. His urine was examined by a physician, who declared it normal. Shortly after this it was examined by another physician, who reported it "in a bad way." He entered a hospital in the city of his residence and appears to have been judiciously treated, but did not improve.

He then came under my care as stated, September 14, 1896.

On admission he was edematous as to his feet, legs, and trunk, and there was effusion into both pleural sacs. His urine was very scanty, only eleven ounces being passed during the first twenty-four hours of his residence in the hospital. It contained three-fourths its volume of albumin and large numbers of tube casts, including granular fatty casts, pale granular and hyaline casts, with numerous granular fatty (compound granule) cells and leucocytes.

The treatment instituted was a drachm of Epsom salt every morning before breakfast, with digitalis tincture in ten-minim doses every six hours. His diet was light, including toasted bread, with milk as a drink—not an exclusive milk diet. At the end of three weeks (October 6) I noticed that our efforts to secure diuresis had been almost failures. The daily output of urine ranged from ten and a half to eighteen ounces—and only once the last amount—up to the 21st of October. Digitalis was suspended and reordered fortified with solution of acetate of ammonium without effect. Sparteine was no more efficient than digitalis. On the other hand, elimination by the bowels was very active, from two to six stools daily being recorded. To this, rather than to the renal secretion, must be ascribed the slight improvement noted on October 6, consisting in a slight reduction in swelling and a drop in the volume of albumen to one-half as contrasted with three-fourths on admission. On the 12th we had recourse to theobromine in fifteen-grain doses three times a day. On the 16th, theobromine appearing to have disturbed his stomach, it was discontinued. On the 15th massage was commenced, and on the 20th we noted: "The massage seems to be working well with Mr. A. The effect has been not only to reduce the swelling but also to produce a general increased comfort, while the urine secretion was well maintained. His stools undoubtedly supplement the action of the kidneys in a helpful manner, since the discharges are numerous and almost liquid. His treatment at present consists of massage daily, digitalin one-sixtieth of a grain once a day, increased to-day to twice a day, and a drachm of sulphate of magnesium every morning. We have also modified his diet, withdrawing the milk between meals, and giving him a moderate solid meal with coffee in the morning, and water at noon and in the evening, and oyster broth in the evening."

By the 21st his urine had reached  $23\frac{1}{2}$  ounces; on the 24th  $43\frac{1}{2}$  ounces; on the 25th 33 ounces; on the 27th 48 ounces. On this day it still contained one-half its bulk of albumen with hyaline casts, but the dark granular casts had disappeared. The digitalin, which had been given in doses of one-sixtieth grain twice a day, was tentatively omitted on the 27th. Notwithstanding this the urine continued to rise, reaching 50 ounces on the 31st; 57 on the 1st of November;  $65\frac{1}{2}$  on the 2d; and 70 on the 3d. We concluded, therefore, that the digitalin had had little if anything to do with the diuresis. After this the urine began to drop off, but still kept up to about thirty ounces, and as the dropsy by this time had pretty well disappeared the decline appeared natural. By November 20 there was no dropsy and no signs of effusion in the chest.

Mr. D. had from the beginning a cystitis which gave rise to considerable pus in his urine. This had recently become aggravated. Irrigation was ordered on alternate days, and in a very short time the pus had almost totally disappeared. On the 28th of November the urine, of which there was but  $18\frac{1}{2}$  ounces, contained one-third bulk of albumin and a little pus, but no tube casts. As there was no dropsy we suspected the scanty urine was due to too meager ingestion of liquids, and he was ordered to drink freely of water between meals, and in a few days the secretion had risen to fifty ounces. By the 8th of December the albumin was reduced to a mere trace. On December 12 we noted: "Mr. A. has continued to improve and is apparently well. We note also this day there is a disposition to alkalinity of urine with a tendency to deposit triple phosphate crystals almost immediately after it leaves the bladder." Ten minims of dilute nitro-muriatic acid was ordered three times a day, and in two days this alkalinity had passed away. On the 13th of December he was discharged in apparent perfect health, though there was still a mere trace of albumin. I have examined his urine many times since and found it normal.

This case appeared at one time so desperate, and several times was associated with a headache so severe, that I once thought a fatal uremia imminent. Yet he has recovered apparently completely.

Looking about for the instrument which brought the turning point in his case, I cannot but think it was the massage. From the day this treatment was instituted improvement set in. It was continued up to the time

of his discharge. Massage was used in the case of Mr. W. first reported with great comfort, and aided also to reduce the dropsy, but the more intractable nature of his disease made all improvement temporary. I do not forget that Mr. A. received digitalin at the same time up to one-thirtieth grain a day, but I have so constantly failed in other cases to produce any effect with the drug that I cannot think it had anything to do with the good effect.\*

One of the most valuable lessons taught by the last case, and in fact by all of them, is that each case is a law unto itself and that we cannot lay down any one rule of treatment even in cases exhibiting much similarity, while the individual too should come in for a full share of consideration. Thus I have had patients to whom massage was intolerable and to whom the Nauheim bath was a source of terror.

I hope I have shown that much may be done for these intractable cases by a judicious treatment, and that by patience associated with abundant resources an apparently hopeless case may even recover and the word "cure" in its broadest sense be applied to its management. Timely and judicious changes in treatment are most important in these chronic cases, while hasty and thoughtless changes are harmful.

*THE VALUE OF POTASSIUM PERMAN-  
GANATE AS AN ANTIDOTE FOR  
OPIUM AND ITS ALKALOID,  
MORPHINE.*

---

BY E. Q. THORNTON, M.D.,  
Demonstrator of Therapeutics and Pharmacy in the Jefferson  
Medical College of Philadelphia,

AND

CHARLES A. HOLDER, M.D.,  
Assistant Demonstrator of Pharmacy.

---

Dr. William Moor, of New York, has been given the credit of introducing potassium

---

\*I have been a good deal discouraged, as I suppose many have, by the variety of products which have received the name digitalin. These have been mentioned in a note on page 3. I cannot forbear, however, calling attention to a recent paper by Dr. Henry Beates on "The Use of Digitalin with Reference to Dose," published in the *Journal of the American Medical Association* of July 26, 1897. In this paper Dr. Beates reports some remarkable results from the digitalin (German, Merck) in doses of one-tenth to one-half grain, far exceeding amounts which one would consider safe in a drug which, though of acknowledged uncertainty, has heretofore been regarded as a powerful poison. Knowing Dr. Beates as I do, and having confidence in his judgment and reliability, I shall take an early opportunity to make a trial of his method.

permanganate as a chemical antidote to morphine, and he demonstrated beyond a doubt the antidotal properties of this substance when both were administered by the mouth. The power of potassium permanganate to oxidize morphine and some other alkaloids, when brought in direct contact with them, is not to be disputed, and if administered by the mouth in dilute solution while opium or its alkaloids are still in the stomach, immediately oxidizes them and thereby prevents toxic effects from being manifested. The originator of the antidote as well as several other physicians appear not to be satisfied with the beautiful and satisfactory action of the antidote in neutralizing the effects of morphine when administered by the mouth, but put forward the extravagant claim that even when given hypodermically potassium permanganate was a valuable antidote to opium and its alkaloids.

For the drug to be of value when given hypodermically there are but three possible ways in which it may overcome the poisonous effects of opium: First, chemically, by coming in contact with the alkaloids in the blood and thereby oxidizing them; second, by acting as a physiological antagonist; and third, mechanically, by giving rise to severe pain which follows the injection of potassium permanganate, thereby assisting in keeping the patient awake.

With the idea of substantiating or disproving these claims, as far as it is possible to do so by study upon animals, a series of experiments were carried out in the Laboratory of Experimental Therapeutics of the Jefferson Medical College. It was found that the approximate fatal toxic dose in dogs was about .600 to .700 grammes of morphine sulphate per kilogramme of body weight, but to make sure that a full poisonous dose was given in each case, the quantity of morphine administered subcutaneously in each of the recorded experiments was .750 grammes per kilogramme of body weight. This dose was usually fatal in from two to three hours.

The following records will show that six dogs were given, subcutaneously, toxic doses of morphine, all dying in from two to three hours. Then five dogs were given toxic doses in the same manner, and followed by subcutaneous injections of potassium permanganate in from five minutes to an hour, and still all the animals died as promptly as if no permanganate had been given.

Next, a dog was given less than a toxic dose of morphine hypodermically and the

antidote given. The effects of the morphine were the same as if no potassium permanganate had been administered.

Finally, a dog to which no morphine had been administered was given twenty grammes of potassium permanganate subcutaneously, and the only effect noted was that the injection gave rise to symptoms of very severe pain, which passed off in about thirty minutes.

One grain of potassium permanganate is said to neutralize one grain of morphine, but in test tubes at least two grains of potassium permanganate are required to reduce one grain of morphine, and the following recorded experiments were conducted upon this basis.

The general effects of morphine upon all the dogs to which it was given were similar to those recorded in experiments No. 1 and No. 7. On account of the large quantities of morphine required to produce death in dogs, the amount of fluid to be injected was too large to be administered with a hypodermic syringe, so a fountain syringe to which was attached a small cannula was employed for this purpose.

It is to be noted that dogs may be given enormous quantities of potassium permanganate without being thereby poisoned. (See Experiment No. 13.) As the potassium salt is only soluble in 1 in 16 of cold water, as much as 350 to 400 cubic centimeters of water was required to dissolve the larger doses of permanganate, but as the solutions were always made in warm water and given by means of the fountain syringe, with trocar and cannula attachment, and injecting into several parts of the body, no difficulty was experienced in dissolving or administering the chemical.

AUGUST 11, 1897.

*Dog No. 1.—Weight 12 kilogrammes.*

- 11.55 A.M.—Nine grammes morphine sulphate was given subcutaneously, using a fountain syringe and a small cannula. Dog became quiet and languid almost immediately, lying quiet for about twenty-five minutes.
- 12.45 P.M.—Rises up and attempts to walk. There is considerable tetany in all the muscles.
- 1.05 P.M.—Tetanic convulsion.
- 1.20 P.M.—Severe tetanic convulsion.
- 1.25 P.M.—Severe tetanic convulsion, relaxation, shallow rapid respiration, then breathing ceased altogether. Heart continued beating for about two minutes.
- 1.30 P.M.—Dead.

AUGUST 12, 1897.

*Dog No. 2.—Weight 16 kilogrammes.*

- 11.55 A.M.—Twelve grammes morphine sulphate subcutaneously.
- 2.00 P.M.—Dead.

AUGUST 17, 1897.

*Dog No. 3.—Weight 14½ kilogrammes.*

- 11.05 A.M.—Ten grammes morphine sulphate subcutaneously.  
1.05 P.M.—Dead.

AUGUST 17, 1897.

*Dog No. 4.—Weight 8 kilogrammes.*

- 11.25 A.M.—Six grammes morphine sulphate subcutaneously.  
2.05 P.M.—Dead.

AUGUST 18, 1897.

*Dog No. 5.—Weight 17 kilogrammes.*

- 10.25 A.M.—Twelve and a half grammes morphine sulphate subcutaneously,  
2.10 P.M.—Dead.

AUGUST 20, 1897.

*Dog No. 6.—Weight 12 kilogrammes.*

- 2.00 P.M.—Nine and three-fourths grammes morphine sulphate subcutaneously.  
5.45 P.M.—Dead.

AUGUST 25, 1897.

*Dog No. 7.—Weight 13½ kilogrammes.*

- 10.40 A.M.—Ten grammes morphine sulphate subcutaneously.  
10.55 A.M.—Twenty grammes potassium permanganate subcutaneously.  
11.20 A.M.—Considerable tetany in all muscles.  
1.10 P.M.—Severe tetanic convulsion, relaxation, rapid shallow breathing.  
1.13 P.M.—Respiration ceased; heart beat for about two minutes. Dead.

(It will be seen that not only did the alleged antidote not prevent death, but it did not modify the effect of morphine in any respect.)

AUGUST 25, 1897.

*Dog No. 8.—Weight 16½ kilogrammes.*

- 3.58 P.M.—Eleven grammes morphine sulphate subcutaneously.  
4.05 P.M.—Twenty-two grammes potassium permanganate subcutaneously.  
6.00 P.M.—Dead.

AUGUST 26, 1897.

*Dog No. 9.—Weight 6½ kilogrammes.*

- 10.25 A.M.—Five grammes morphine sulphate subcutaneously.  
11.00 A.M.—Twelve grammes potassium permanganate subcutaneously.  
2.00 P.M.—Dead.

AUGUST 27, 1897.

*Dog No. 10.—Weight 6½ kilogrammes.*

- 3.30 P.M.—Four and eight-tenths grammes morphine sulphate subcutaneously.  
4.30 P.M.—Ten grammes potassium permanganate subcutaneously.  
8.00 P.M.—Dead.

AUGUST 30, 1897.

*Dog No. 11.—Weight 12 kilogrammes.*

- 10.45 A.M.—Ten grammes morphine sulphate subcutaneously.  
11.15 A.M.—Twenty grammes potassium permanganate subcutaneously.  
3.15 P.M.—Dead.

AUGUST 30, 1897.

*Dog No. 12.—Weight 16 kilogrammes.*

- 10.45 A.M.—Eight grammes morphine sulphate subcutaneously.  
11.00 A.M.—Sixteen grammes potassium permanganate. Animal recovered completely.

This animal did not receive a toxic dose, which would have been thirteen grammes. The administration of the potassium permanganate in no way modified the usual effects of the morphine.

SEPTEMBER 3, 1897.

*Dog No. 13.—Weight 6½ kilogrammes.*

- 3.35 P.M.—Twenty grammes potassium permanganate given subcutaneously. Symptoms of very great pain were occasioned by this injection, and it continued for about thirty minutes. At the end of that time the animal drank water, walked around the room, and with the exception of some fright appeared to be in normal condition.

In these experiments dogs Nos. 1, 2, 3, 4, 5, and 6 received full toxic doses of morphine sulphate subcutaneously, and all died within a few hours. Dogs Nos. 7, 8, 9, 10, and 11 received full toxic doses of morphine sulphate subcutaneously, which was followed in periods ranging from a few minutes to an hour with potassium permanganate given subcutaneously; these animals also died as promptly as those which received no permanganate, nor did the poisonous effects of morphine appear in any way to be modified. One dog (No. 12) received less than a toxic dose of morphine, and, although followed by permanganate, it did not appear to modify in any way the usual non-toxic effects of morphine.

Lastly, a large dose of potassium permanganate was given subcutaneously to a dog which had not received morphine; and with the exception of the pain, which lasted for about thirty minutes, the animal appeared to suffer no inconvenience, and recovered fully. These experiments lead to most serious doubt as to the efficiency of potassium permanganate as an antidote to opium or its alkaloids when given hypodermically.

---

*SOME EFFECTS OF CANNABIS INDICA IN LARGE DOSE.*

---

BY ROBERT C. BICKNELL, M.D.,  
New York.

---

That cannabis indica as encountered commercially is extremely variable in activity is a matter of common knowledge. This applies alike to the crude drug and to all preparations made from it. It is also generally understood, I believe, that the effects arising

from the ingestion of even large doses of a potent preparation are likely to be alarming rather than dangerous, and that no case of poisoning which resulted fatally has as yet been recorded. A temporary neglect of the facts of the former statement, as a consequence chiefly of a realization of the truth of the latter, resulted in my passing through a series of experiences the sensations of which I wish to record, as embodying some features of the drug's effects not generally described, and as going farther than such recorded experiences have hitherto been carried.

I had noted with interest the account of Dr. H. C. Wood's experiences as given in his work on Therapeutics. The preparation which he had taken was made, I believe, from the American variety of cannabis. I had taken previously an extract made by an American house, gradually increasing the dose until five grains had been taken with scarcely perceptible effect, and recall giving within the space of three hours fifteen grains to a boy of seventeen with only slight drowsiness resulting. Wishing to avoid the tedious increase from one-eighth grain up, as in the previous case, I took at once three grains of an English extract. This preparation was quite soft, of a handsome green color, taken from a freshly opened ounce jar, and was put into a gelatin capsule. The capsule was swallowed at 5 P.M. No effect was noticed until nearly three-quarters of an hour had passed, when a slight frontal headache was felt, dull in character and lasting only a few minutes. At 5.45 I was writing, when at the end of a sentence the right hand was suddenly jerked upward, slightly impairing the symmetry of the writing. A slight haze now became perceptible about the margins of the field of vision; the pulse was noticed to be somewhat accelerated, full, and strong. On being spoken to there was a perceptible interval before complete comprehension of the words, the mind seeming to halt a little time before acting. Answering speech was also slow, and after a short time was somewhat confused, not greatly so, but words would become transposed in a sentence, requiring two or three trials to get them in their proper places. The haze gradually grew centerwards, until by 6 P.M. only the object looked at could be seen, all the surrounding field being dark as by a shadow from the circumference. Looking at my hands the fingers seemed enormously long and quite large and were moved with perceptible effort—the move-

ment following an interval, and with a jerk, as if the impulse was delayed in transmission and reached the extremity all at once, not gradually as is usual.

With the beginning of the impairment of vision the muscles at the back of the neck began to be painfully contracted, the contraction beginning with those attached to the occiput, gradually extending downward, and including the muscles of the back until marked opisthotonos resulted. This contraction was tonic and relaxed only when violent friction was applied over the affected muscles.

The pulse was now 100, temperature normal, the respiration slightly hurried, though this may have been owing to some nervousness which now became manifest. There was a sense of extreme tension all along the spinal column.

There were no visions up to this time, and no pleasurable sensations whatever were experienced throughout. At this time I began to have an impression of duality. I was fully aware that I was going through this experience, yet could not rid myself of the impression that I was witnessing it in another. Gradually I got farther away from reality, occurrences being given an interpretation quite foreign to their actual significance. For a long time I could bring myself back to a full realization of everything by an effort of will, a stronger effort being required each time until finally occurrences—all except the most pronounced impressions—were wholly lost sight of. Until after 6 P.M., walking was perfectly steady, and anything directly looked at could be seen, though near objects seemed quite far away. The sense of the duration of time also became altered; a minute seemed as long as an hour almost, and the passing of the minute hand of the clock from one figure to another seemed to require an interminable time.

At 6.15 I lay down, and surrounding objects and subsequent sounds became merely a part of a confused series of visions, many quite vivid for the time but disconnected and too numerous to describe. I recall that at one time I saw the earth free in space, and comprehended all the laws which maintained its position in the universe with its numerous relations to other bodies, and perceived the result of every act, however trivial, even to the ultimate end of time. Every result, direct and indirect, was perfectly clear with but slight mental effort. Mixed with these ideas were other impressions; views of the room in

which I was, and of the people about me, and trains of thought doubtless started by occurrences which I did not notice. Much of the imagery was quite fantastic, though the sensations were rather of a painful and disagreeable nature. I was aware of any violent movement or loud noise during the whole time. The teeth were firmly set, it being impossible to force liquids into the mouth, and frequently strong convulsive movements affected chiefly the upper extremities, occasionally involving all the muscles of the trunk.

I regained rational consciousness about 7 P.M., remaining drowsy and dazed for four hours longer, though I comprehended all that was passing during this time. At 11 P.M. I went to sleep, waking at 7 A.M. next morning feeling none the worse for my night's experience.

Phenomena which I thought worthy of note were: the existence of muscular contractions, followed later by violent convulsive movements, due evidently to action of the drug on the spinal cord. This was one of the most notable features of the whole experience, yet I do not see that such action is at all prominently mentioned in the various articles upon the subject which I have read. This effect was early manifested and was conspicuous throughout. Aside from the acceleration of the pulse-rate and a feeling of fulness in the artery at the wrist, there was just previous to the occurrence of unconsciousness a sense of extreme tension in the abdominal blood-vessels, they feeling distended almost to bursting. This endured for some time. I did not have the feeling of foreboding or fear of impending death, mentioned by Dr. Wood. At no time did I feel fearful of fatal result. After some hours the urine was very much increased in quantity, apparently about double the usual amount being passed for the time between 6 and 11 P.M.; after that it was not noticed as being unusual. No constipation resulted. I thought at one time that the mouth was very dry, as if the secretion of saliva was arrested, but after I became conscious there seemed to be no alteration in this secretion.

These are my own sensations. A physician who saw me while I was unconscious says that my pulse was feeble and respiration shallow, so that he feared collapse. As he applied an electric battery and gave a few injections of ammonia and brandy I presume he really had this impression. Shortly after this I "came to" quite suddenly.

### *THE TREATMENT OF INEBRIETY.*

By A. L. BENEDICT, M.D.,  
Buffalo, N. Y.

It is somewhat inconsistent that the person overcome by one drug should be in a different legal status from that of the one under the influence of another; yet the frequency of alcoholic intoxication, its tremendous financial and social effects, and the organized effort to warn against indulgence in this drug, justify the State in using means which it does not apply to the victim of the morphine or cocaine or other narcotic habit. Thus, while personally admitting that alcoholism is a disease, we believe that it is practically necessary to consider it as a crime also.

It is impossible to draw the line between the fool and the imbecile, between the wicked and the moral pervert, between the man who is quick tempered and the one who is hysterical, between the man of weak will and the one dominated by a habit. Yet the practical appreciation of degrees of difference which cannot be interpreted in any general terms is what gives one a superior understanding of the means to be employed in the treatment of the inebriate. It must be remembered that inebriety is not the same condition in all persons. The practical management of the case depends on the answer to these questions, which are often badly confused by temperance speakers: Does the man drink from love of the taste of liquor? Does he drink from love of the physiological effect? Does he drink because his life is so miserable that partial or complete unconsciousness is pleasanter than sentient existence? Does he drink because, for none of these reasons, alcohol possesses a mastery over him which he cannot shake off? Strange as it may seem to some abstainers, a man seldom uses liquor to excess because he likes the taste of it, as he would like fruit or candy or some more substantial article of diet and, therefore, would eat too much of it. Much more frequently alcoholism is sought to the degree of mild stimulation, and the partaker, having lost some of his power of self-control, then continues to imbibe and passes into a stage which, of itself, has no attraction for him and often is positively revolting to his tastes and judgment when he is capable of sober thought. When a man, or woman, uses liquor for the sake of obtaining oblivion, the hope of cure is small. It is evident that if the individual's personality has become so distasteful to himself that he cannot endure self-association,

that his memories are bitter and tinged with disgrace, the temptation to drown those memories will recur, in spite of treatment; and, humanly speaking, the cure of the alcohol habit is worse than the disease. Cure in such cases is simply a matter of asceticism, unless the primary cause of inebriety has changed to one of the other motives to drink which we have mentioned. In not a few instances persons who like neither the taste nor the action of alcohol, and who are not drawn into the habit from mere social motives, are unable to resist the attractions of liquor. If we could be sure of the good faith of persons who sue for damages claiming to have been influenced by hypnotic power to perform acts contrary to their volition, we should have a close analogue to this form of inebriety. Sometimes the social element seems to be almost the only factor in producing inebriety, the patient suffering relapses only from the more or less deliberate temptation of acquaintances. Sometimes, too, several causes act simultaneously to determine over-indulgence in alcoholic beverages.

If we can be sure that the case in question is of the comparatively rare type of taste-attraction, two courses are open: we can either give some comparatively harmless substance which shall serve as a substitute, or we can make the liquor itself distasteful by combining with it some nauseous substance which shall produce so profound a mental impression as ever afterward to be associated with the taste of the liquor, or we can simply tire the patient of the liquor by giving it protractedly without resting the taste-bulbs by other impressions. The first method consists in the use of some pungent gum or fruity substance or chocolate, the stimulation of the alcohol being represented by iris, capsicum, caryophyllus, etc. The second method is carried out by mixing almost any emetic with the liquor, being careful not to defeat our end by obtaining too prompt emesis. The third method is used in some of the prisons of Scandinavian countries, the culprit and patient being fed with bread dipped in wine till the alcoholic liquor becomes loathsome. It is said that this method is curative even when the cause of inebriety is something else than the gratification of taste. We fear, however, that the loathing would soon disappear, just as it does when disgust at some solid food has been appeased by variety.

In other cases, we believe that the secret of success consists in substituting for the will of the patient some effective means of con-

trol, actual confinement being usually necessary. The Keeley institutes have most happily combined surveillance without actual incarceration, suggestion, stimulation of the patient's own will-power, supporting medication, and medication tended to excite disgust at the taste of liquor. That they are unethical there is no question; that they have done some good no impartial observer can deny; that they have not always cured is established by numerous recorded backslidings. The patient loses his desire for whiskey and apomorphine, and, fortunately, he is a long time in learning that the drink of whiskey and the injection of apomorphine are independent factors which may be separated outside the hospital. He is thoroughly imbued with the fear that a return to alcoholic beverages will prove immediately fatal, and it takes him months before he overcomes this fear or is tempted into testing its validity. Once having learned that the fear is groundless, some relapse into drunkenness; others have so far recovered their will-power and their self-respect that they continue "cured." As regards drugs, strychnine and atropine fulfil all but special indications for supplying the "bracing" effect of alcohol, as far as anything on earth can take the place of alcohol for one who has learned to use it to excess.

We believe that there is urgent need for institutions midway between hospitals and penitentiaries, at which every one can be treated for alcoholism, according to his means. We believe that, without the expense of the so-called "cures" and without their objectionable methods of dealing with ethical questions, institutions may be conducted which shall be under the management of competent members of the regular profession and which will secure good results in relieving those inebriates who really desire to be cured and are willing to lend their own efforts to support those of the physician.

Finally, unprofessional as it may seem to advocate that physicians should make personal use of physiologic and hygienic knowledge, we would remind our readers that our own profession is one of the most important sources of drunkards, and that the danger which has been realized in their case is potentially present in that of every "moderate drinker." Plainly speaking, we believe it is disgraceful that nine-tenths of our profession should use alcoholic liquors purely as beverages.

*USEFULNESS OF ARSENIC IN THE  
TREATMENT OF CUTANEOUS  
MALADIES.*

BY J. ABBOTT CANTRELL, M.D.,

Professor of Diseases of the Skin in the Philadelphia Poly-  
clinic and College for Graduates in Medicine; Der-  
matologist to the Philadelphia Hospital  
and to the Frederick Douglass  
Memorial Hospital.

Peculiarly—but undoubtedly—arsenic has accepted the foremost place in the armamentarium of the empirical physician, and while this blind confidence has been extended over a considerable space of time it has not been without its results. To-day we are in a fair position to divert it into the proper channels. All through this empiricism the action of the drug has ever been under the critical eye of some acute observer. After many trials we are placed in a position to know just exactly what this or that drug will or will not do. This has been the case with arsenic. All drugs have to pass through the same amount of study, and it is not until they have been tried that we can state their effect. Even to-day this fact can be substantiated in relation to arsenic in the treatment of cutaneous outbreaks. Many affections of the skin are placed under treatment by arsenic and the affected person becomes worse instead of better, and this can be accounted for only by the fact that the drug has been advised injudiciously.

Of the affections of the skin in which arsenic has proved of advantage the number is rather limited, but often we may find that by some complication of the malady it may be wisely incorporated with other measures. I will mention these affections as we progress in our work.

Arsenic is not a new remedy, but yet new fields may be opened to it by more careful observation. That it is a powerful drug and may induce harm if improperly advised is well understood. But carefully given in selected affections it has a decided field of usefulness. This field of usefulness is varied, as will be shown by the many good results following both its internal and external administration. Internally it has a tonic effect, increasing the quality of the blood and thus exerting a restorative influence. Externally it produces inflammation, removes hypertrophies, has a stimulant quality, and destroys abnormal tissue such as is found in epitheliomatous degenerations, lupus, and certain other destructive diseases.

The preparations of arsenic useful in der-

matology comprise most of those contained in the Pharmacopœia, but from choice this list is greatly decreased in the work of certain individuals who have found that this or that preparation gives the most satisfaction in the class of cases presented to their view; but still another class of practitioners may receive good results with the preparations thus discarded by their fellows. Internally the arsenous acid and Fowler's solution receive the greater portion of the prescribing in this country, while the acid with liquor arsenicalis play the more important rôle abroad. The liquor arseni et hydrargyri iodidi (Donovan's solution) and liquor sodii arsenatis (Pearson's solution), both have their friends. Externally the arsenous acid does the greater part of the work, while liquor potassii arsenitis (Fowler's solution) often proves advantageous.

Internally arsenic is advisable in affections of the skin which present hypertrophic manifestations such as psoriasis, or where the blood has become changed as in pemphigus. Externally it removes growths of tissue such as in lupus, thus showing a caustic effect, or where degeneration has occurred as in epithelioma.

*Psoriasis.*—This affection is undoubtedly one in which arsenic performs the greatest number of cures, and one in which the drug usually acts beneficially; but as there are cases in which the drug has little if any effect, it is wise to remember that it is not judicious to advise it where the disease is in its acute stage, or in those cases in which the remedy has been repeatedly used. Failures often occur by its injudicious administration. The dose required is usually one in which the characteristic effect is neared, and usually begins at a small figure, increasing until the desired effect is noticed.

*Lichen Planus.*—This condition also is greatly benefited by the use of arsenic, and whether it is an acute case or whether the affection is of long standing the drug likewise produces curative results. The dose must be sufficient to affect the condition, and may reach large proportions in some cases. I can recall one in which it was found desirable to give three grains of the arsenous acid during the course of twenty-four hours.

*Eczema.*—Arsenic is rarely ever beneficial in this cutaneous eruption, but occasionally cases do arise in which its effect is welcomed. Those cases of long standing in which all indicated measures have been exhausted and those in which we are confronted with

hypertrophic manifestations are both benefited by its judicious administration. Otherwise it usually does positive harm.

*Acne, Acne Rosacea.*—Both of these conditions are affected curatively by the internal use of arsenic, either in the form of arsenous acid or that of the Fowler's solution. In cases of these affections, where there is nervousness present as a complication or where general tonics are called for, the drug is advisable. In those cases in which the type of manifestation is of the popular variety and in which induration is present, or where the pustular form is observed with some thickening around each little lesion, arsenic is demanded.

*Pemphigus.*—Arsenic is one of the few drugs which have any beneficial effect upon pemphigus, and to get this result it is necessary to begin with a small dose and increase until a distinct impression is made, or at a point where it is noticed that the tolerance of the affected person is reached.

*Furuncles.*—The effect of arsenic upon furuncles is that of a tonic upon the general system. It often does considerable good in cases of incessant furunculosis. It assists materially in placing the person in a position to resist the attack of furuncles.

*Mycosis Fungoides.*—From all of the remedies that have been used in the treatment of mycosis fungoides, the selection of arsenic is the only judicious measure. It may be used internally by the system or by hypodermic injection. Beginning with small doses the quantity is increased gradually until one sees some favorable result. But it is not wise to place too much dependence even in this drug, because many failures will result on account of the great fatality of the affection.

*Erythema Multiforme.*—This remedy performs a very important duty in the treatment of multiform erythema of the more chronic stages, and should be found curative in many cases. The dose should vary with the chronicity of the trouble.

*Vitiligo.*—As vitiligo is an affection of the pigment of the skin it will be found that arsenic often produces some slight results in its restoration, but too much dependence must not be given to it.

*Lichen Ruber.*—Lichen ruber is often benefited by the use of arsenic in its early career, but afterwards no effect is produced by its administration.

*Sarcoma.*—Sarcomatous conditions of the skin have been benefited by the internal ad-

ministration of arsenic, but the number of failures far outrank the number of cures.

*Epithelioma.*—In the treatment of epithelioma it is possible that arsenic has its greatest field of external usefulness. This fact is made of great importance by the so-called "cancer doctors," who employ it in the treatment of this condition. Of the preparations usually advised there are a number of ointments which may have decided curative properties, but there is an incessant pain produced by its application, and these cancer doctors state that "it is now drawing out the cancer." Marsden's paste is made with arsenous acid and gum acacia, and is one of the best measures that may be adopted. If patients will stand the pain—and there are a great many that would rather than have an operation—a cure may be expected, but it may be necessary to keep the application in contact for an indefinite period or numerous delays in treatment must be occasioned by this excessive pain, thus prolonging the case for a very long period.

*Lupus Erythematosus.*—The external application of Fowler's solution has cured some cases of lupus erythematosus. The first condition produced by this remedy is an inflammation, which gradually subsides, with possibly a marked change in the lupus area. It cannot be relied on in many cases.

Other than in the diseases mentioned above arsenic has little or no effect, and it is not wise to waste time in prescribing it. Occasionally cases will arise in which it may be judiciously given.

---

#### POST-OPERATIVE TREATMENT OF SURGICAL CASES.

---

BY THOS. LEIDY RHOADS, M.D.,  
Assistant in the Surgical Clinic, Jefferson Medical College  
Hospital.

(Continued from page 817.)

*Retention of Urine.*—The inability of the patient to empty the bladder voluntarily after operation is not an infrequent phenomenon, and whether the retention be due merely to the abolition of the normal reflexes following interference with the central nerve tract, or to the reflex spasmodic action of the sphincters so common after operations about the genitalia, or to obstruction from acute inflammatory engorgement of urethra or prostate, the condition is one that commands the surgeon's urgent attention. The frequency of the occurrence is so noteworthy

as to demand not only a daily inquiry as to the amount of urine passed in the previous twenty-four hours, but also a systematic examination of the suprapubic region by percussion as a matter of routine after all operations of magnitude; for although the element of pain, with marked discomfort, is usually associated with a distended bladder, a subconscious state will remove this monitor of danger, and the voiding of a limited quantity of urine, or a constant dribbling, may be but the overflow from a distended viscus—the incontinence of retention. More often, however, the symptoms of suffering in this condition are so pronounced that early relief is usually sought for by the patient himself.

Shock must always be considered an assignable cause for certain forms of retention, from the accompanying disordered nerve action and the resulting failure of the detrusor muscles; but certain it is that the condition is met with more generally after certain well defined operations, especially those done for the relief of some cerebral and spinal maladies, for anal fistula and hemorrhoids, and for ailments peculiar to the genito-urinary tract itself. It is not uncommon to observe in patients who have had cerebral growths removed, or who have sustained cranial injuries necessitating surgical intervention, that the characteristic globular swelling appears above the pubes within the first twenty-four hours, unless it was previously anticipated with a catheter or other means, and the effects of traumatic irritation to the lumbar spine are well known. The ligation of a single pile and the section of the spermatic cord have brought about a neighboring reflex spasm that persisted for days even under appropriate treatment, and the fresh congestion of the vesico-urethral tract, especially of the prostate gland, which is induced by any operation requiring anesthesia in those who are just recovering from an acute infective inflammation of the urethra, or who are suffering with a latent chronic form of the disease, and which results in a painful retention, is too well known to excite comment. Likewise, the serious significance of the unrelieved condition, the ultimate unavoidable rupture of the bladder, the peritonitis, pyemia, and death, form a clinical picture which it is manifestly the surgeon's duty to avert.

The treatment of the condition will necessarily begin with prophylactic measures before the operation proper, and the surgeon will discover, especially prior to operations near the genitalia, either by careful inquiry, or, if

necessary, by confirmatory urethral exploration, the existence of any obstacle that might later produce complete obstruction. If sufficient time exists, a stricture will be divided or dilated, a urethritis cured, and a prostatic enlargement suitably treated. If the rule were followed by surgeons generally before undertaking serious operations, that it is important that not only should the condition of the kidneys be ascertained by careful preliminary examination of the urine, but that the urinary outlet should likewise be investigated, under strict antiseptic precautions, to determine whether there be any narrowing or pathological alteration of the channel, these precautionary measures would undoubtedly help to reduce the mortality in cases operated upon, who subsequently develop a retention, and which often leads up to a group of inflammatory processes, beginning with a cystitis and ending with a fatal uremia or pyemia.

In considering the treatment of retention after operation, the causes which induce it may be classified as follows:

1. Disordered reflex action.
2. Rekindling of urethral or prostatic inflammation.
3. Sudden closure of a stricture.
4. Acute inflammation or congestion of a hypertrophied prostate gland.

The first class includes those cases of spasmodic retention so frequently met with after operations about the anus and genitalia, and after operations upon the central nervous system, where there is no history of a previous urethritis or of obstruction from stricture or other cause. It is caused merely by a spasmodic contraction of the sphincters, due to loss of control over them from undue irritability either of the central or peripheral nervous reflex; and in the management of these cases an effort should be made to relieve the condition by local applications and antispasmodics, avoiding if possible the passage of instruments, as these tend to increase the irritation and spasm. When it is practicable, the patient should be placed in a hot sitz bath, and directed to pass his water in the bath. The character of the operation will, however, often prevent the carrying out of this plan, and a fitting substitute will be found in a copious hot-water enema, and applications of towels wrung out in hot water placed over the hypogastrium and genitals. These means will usually suffice, especially if the patient hears at the same time the dripping of water behind a near-by screen; but if

this will not produce the desired effect in the course of a half hour, the adult patient is given at a single dose by mouth:

- R Morph. sulph., gr.  $\frac{x}{4}$ ;  
Quinia sulph., grs. x;  
Spts. frumenti,  $\frac{3}{4}$  j.

M.

providing there are no gastric contraindications; and in conjunction with this the Jefferson Hospital mixture:

- R Tinct. belladonna,  $\text{m} \frac{xv}{2}$ ;  
Tinct. ammon. valerianate, f  $\frac{3}{4}$  vj;  
Sodii brom., 3 ij;  
Syr. zingiberis, f  $\frac{3}{4}$  j;  
Aque dest., f  $\frac{3}{4}$  iij.

M. Sig.: Two drachms in water every hour.

in case time still remains to devote to conservative means. Should gastric irritability contraindicate the administration of the above, a suppository of pulverized belladonna one-fourth grain, and pulverized opium half a grain, may be substituted. If at the end of a few hours after beginning treatment the retention is not relieved by these means, a resort to the catheter is indicated. Catheterization must then be carried out with the utmost regard to surgical cleanliness, for catheterization cystitis, as a result of imperfect antisepsis, is not a rare occurrence after the use of unclean instruments for the relief of post-operative retention, and every surgeon has had more or less difficulty in combating this unfortunate added mischief. In a normal bladder, containing normal urine in normal quantity, Pasteur and Lister have shown conclusively the absence of micro-organisms, which reports are corroborated by the ingenious experiments of Cazeneuve and Livon, and under these favorable conditions the mucous membrane of the urethra and bladder may be handled with a certain degree of impunity, the healthy bladder having power to cope successfully with a moderate amount of infection, should micro-organisms be introduced into its cavity. When, however, the vesical mucous membrane is greatly congested, as well as prostate, ureters, and kidneys, from an acutely distended viscus, and when bloody extravasation has taken place within its walls, as is usually the case, quite a different condition presents itself. The conditions are then ripe for infection, and the deposit of a minute quantity of bacteria on its mucous membrane whose function is thus greatly impaired, may prove to be the starting point of a septic process, which has on more than one occasion terminated fatally. It is accordingly of the highest importance that a rigid and thorough technique be ob-

served in catheterizing the patient, not only in the preparation of the instruments employed, but also in the cleansing the hands of the operator and the external genitals of the patient as far as practicable, precisely the same care being exercised as though an open wound were to be inflicted.

It is an unfortunate fact that although the bladder is devoid of bacteria, quite the reverse condition exists in the urethra, and that in introducing a catheter into the bladder the instrument must pass through a canal rich with micro-organisms. The researches of Lustgarten and Rovsing have shown that in the normal urethra myriads of organisms exist, principally the staphylococci and streptococci of the pyogenes type, which will be a particular menace to catheterization, especially when the function of the bladder wall is below par; and so far as is known at the present day there is no germicide that is capable of completely removing these pathogenic organisms from the deep follicles of the urethra. However, clinical experience has taught us that whereas it is not common to have a septic condition follow the use of an unclean catheter in the cases under consideration, it is quite rare, when the external parts and instruments are thoroughly disinfected, to have any unpleasant symptoms develop, so that the significance of the urethral flora is not as grave as might at first appear.

In selecting a suitable catheter for these cases, the soft rubber instrument of Jacque will always stand foremost, as it is the least irritating of the many varieties, but with its peculiar adaptability comes the difficulty with which it is made sterile. Of all the numerous methods devised to accomplish this disinfection, that employed by Professor Horwitz at the Jefferson Hospital has proved to be the most satisfactory. The rule is here followed that cleanliness in dealing with the bladder is just as imperative as in the lying-in chamber, for the possibility of infection is quite as great, and only those methods are employed that have stood the rigid test of long-continued investigation. Catheters are kept on hand in metal boxes, in which sterilization is constantly taking place, so that they are ready for instant use, a sufficient number (eight) for one patient being kept in a single box.

In rendering these instruments aseptic, much stress is placed upon the primary mechanical cleansing with soap and water. They are first scrubbed with Johnston's ethereal soap to remove adherent oil and

dust, and are rinsed thoroughly by holding them under a tap of hot boiled water, until the caliber of the instruments have been freely irrigated. They are then dried with a clean towel or gauze, and placed in the vaporizing box of Guyon, in which a derivative of formol, the antiseptic value of which drug was first pointed out by Trillat, is used as the disinfecting agent. Formol is a concentrated solution of formic aldehyde, of forty-per-cent. strength, and if concentration of the latter is pushed to the extreme limit by evaporation, there is left a white powder known as trioxymethylene, which if exposed to the air gives off dry vapors of formic aldehyde, a powerful antiseptic agent especially valuable in the disinfection of catheters, since it does not destroy the surface with which it comes in contact. By making use of this method the objectionable antiseptics formerly used, in which the instruments were submerged for indefinite lengths of time, and cleansed imperfectly, frequently proving irritating to the urethral canal, are dispensed with. Eight catheters having been dried, they are placed in the metal box above mentioned, which is forty-two centimeters long, ten centimeters wide, and ten centimeters high, and is hermetically closed by a metallic cap with a rubber washer. This box contains two movable shelves made of perforated metal, and in the bottom is a frame upon which is stretched a piece of cloth or absorbent lint designed to receive the trioxymethylene powder, which is sprinkled in a shallow layer over the entire surface, and the temperature of the surrounding atmosphere is kept at about 60° F. Twenty-four hours is required to sterilize large calibered catheters, forty-eight hours for catheters of fine caliber. The slow evaporation of the trioxymethylene keeps the atmosphere dry, thus avoiding softening of the instruments. The number of catheters selected (8) is usually sufficient for all cases, even should the retention continue over a number of days, the patient being catheterized every six hours. Four catheters are placed upon the upper shelf and four upon the lower, the trioxymethylene powder spread in place, and the box stored away until the catheters are needed. Each time catheterization becomes necessary one instrument is taken from the upper shelf, and having been used, is put aside; the next day the four catheters that have been used are scrubbed and rinsed, dried thoroughly, and put back on the upper shelf, those on the lower shelf being next

utilized, the cap of the box being removed and replaced as rapidly as possible.

The disinfection of the hands of the surgeon and the genitalia of the patient is of no minor importance. The surgeon scrubs his hands and forearms with soap and water, rinses them with sterilized water, carefully cleanses the nails, and finally uses the brush in the mercuric chloride solution 1:1000, or other antiseptic of equal germicidal strength. Regard for the most scrupulous care in this particular is imperative; the so-called antiseptics of the "bichloride doctor" (he who merely dips his uncleansed hands into bichloride solution, and considers them disinfected) is a surgical myth. No less an attention to detail will suffice than that which is required where other important cavities are invaded by operative means. The penis in the male is cared for in the same manner, special attention being given to the glans and foreskin, and the orificium urethræ, which are carefully mopped with pledgets of sterile cotton wet with mercuric chloride solution 1:1000, after the preliminary use of soap and water; and if especial caution is heeded the urethra may be irrigated with a boric acid solution ten grains to the ounce. Aseptic towels are spread over the patient's thighs and abdomen, leaving the penis uncovered, a catheter is selected from the Guyon box, rinsed in boric acid solution, lubricated with liquid vaselin which has been sterilized by heat (glycerin and carbolic solutions irritate after continued use), and passed into the bladder. If much difficulty is experienced in passing the soft rubber instrument, the device of Professor Brinton is made use of by passing a thin whalebone previously disinfected by scrubbing it with soap and water and with bichloride solution, into the catheter to the eye in order to stiffen the shank and leave the point free. When the point of the catheter approaches the bladder the whalebone is withdrawn an inch to avoid possible injury to the bladder wall from projection of the end of the whalebone through the opening in the catheter. The instrument is then pushed into the bladder, the whalebone removed, and the urine drawn off into a vessel. There is no danger in emptying the bladder completely in these cases, and as there is usually an associated polyuria, the catheter must be used every six hours until spontaneous evacuation occurs. While the dangers of risking an infection are present every time the instrument is used, it has been happily pointed out that "when practised with due

regard to cleanliness these catheterizations prevent cystitis, since they relieve the venous engorgement which is a most potent predisposing factor to the infection" (White and Martin).

In women the same methods must be used in relieving the retention, though instead of making use of the soft rubber instrument the ordinary glass catheters can be used, after being sterilized by boiling. It is particularly of importance that the labiæ and region about the meatus be thoroughly cleansed before passing the catheter, and that this should not touch the neighboring structures before entering the urethra; hence the wisdom of using the catheter by the aid of sight and not depending upon the sense of touch alone. Catheterization thus performed is devoid of any serious consequences, even though it be practised for a number of days. The patient should, however, all the while be encouraged to empty the bladder as soon as possible without the use of an instrument.

(To be continued.)

#### CHELIDONIUM IN CANCER.

A report of a discussion on this subject in the Russian Pirogoff Surgical Society is published in *Vratch*, No. 32, 1897. Shulgin treated five cases of cancer by internal administration and subcutaneous injection of extract chelidonii majoris into the growth. The injections were made at intervals of one and two days with a fifty-per-cent. solution of the extract during about three months; at the same time fifty grammes of the extract was given internally every day for fifty days. Reaction was only local. The growths became more succulent, were breaking down, and a gray fluid and detritus discharged from the interior. A general reaction was noticed in a sixth case, that of an out-patient, a habitual drinker, after two injections. Chelidonium must not, in Shulgin's opinion, be regarded as a specific for cancer, but its destructive action upon it cannot be denied. Religioki made injections at the hospital at Briansk with fifteen grammes of a fifty-per-cent. solution every four or five days, not into the substance of its growth, but into its neighborhood, giving at the same time internal doses of seventy-five to ninety grammes daily. He observed a case of cancer of the breast, the size, consistence, and shape of which became totally changed after internal administration of the drug for six weeks, and it could afterwards be easily removed by oper-

ation. A microscopic examination showed shriveling and breaking down of the cells in the growth, one part of the white corpuscles constituting a line of demarcation between the dead and the healthy tissue, the other infiltrating the growth, which was being converted into detritus, thus favoring the breaking down of the new growth cells. Chelidonium, he thinks, has a beneficial effect in many cases of cancer. Minin, who tried the remedy in four cases (two of carcinoma esophagi, one of cancer of the liver, and one of cancer of the tongue), found chelidonium of no use. Trojanof had not seen any benefit of it in cases of inoperable cancer; the patients were made rather worse owing to the reaction. The diminution in size of the growth is not to be doubted, but this is due to absorption of the products of inflammation set up by the injections. Turner reserves his opinion, and thinks that in cases of cancer of the lip thorough extirpation is to be preferred. Vreden thinks that the treatment with chelidonium does not respond to the fundamental condition of therapeutics—*non nocere*. The injury caused by the general reaction is undoubted. Vubbotin, who has tried chelidonium in operable cases, considers it worthy of further trial. Zenenko, in eleven cases of cancer of the alimentary canal, did not notice any benefit from its internal administration in doses of sixty to ninety grammes. The patients complained of increased pains and difficulty of digesting food. The subcutaneous application in some cases of cancer of the breast and lower lip caused local and severe general reaction, with chill and prostration, which lasted for twenty-four hours. He considers chelidonium to be like caustic—a powerful local irritant, causing necrosis. Vertogradof tried the effect of injections (having been made aseptic) upon a healthy man (himself) and found it caused a powerful local reaction; inflammatory edema of the size of the palm of the hand, which disappeared after a few days, leaving the skin folded and covered with rhagades and very painful. On the spot where the injection was made there remained a nodule for a long time. The general reaction is not less severe. Ratimoff has noticed cachexia develop and the patients lose weight under treatment with chelidonium. The induration of the base of the cancer remains unaltered; the injections are very painful. He also thinks the remedy acts merely as a caustic.—*British Medical Journal*, Sept. 18, 1897.

### THE MECHANICAL TREATMENT OF LOCOMOTOR ATAXIA.

Whenever a new plan of treatment is suggested or recommended for the treatment of a grave disease which is considered incurable it is at once, and very properly, tried and tested by almost every physician who has under his care cases of the malady and the necessary drugs or apparatus for the test. Notable examples of such tests might be cited did space permit, and every one who has been interested in medicine for a few years can count upon his fingers instance after instance in which a remedial measure has been advanced by some clinician and after a period of trial has become obsolete. These experiences have caused therapeutic nihilists to doubt the value of every new method of treating disease and to laugh at the enthusiasm of their fellows who have tried the novel plan. As a matter of fact the so-called excess of enthusiasm to try something new is praiseworthy; by such trials the good is speedily separated from the useless in therapeutics, and we quickly arrive at the true value of a so-called discovery.

Sometimes the plan proposed is cast aside because it is found utterly useless, but far more frequently it is retained by the well-informed as being suitable for a given number of cases which present certain lesions or symptoms. This is quite true of the so-called "suspension treatment" of locomotor ataxia. Heralded as a cure-all for a disease which from its very nature must be incurable, it was speedily found to be useless for the purposes of cure, futile for the arrest of its progress in active cases, and useful only for the relief of certain annoying symptoms in some instances.

This suspension treatment, by means of which the patient was swung off his chair by a harness and pulley attached to his head, was supposed to stretch the spinal column and the cord and so to produce its good effects, but this was never positively proved by accurate experimentation, and interest waned till it seemed unlikely that any one would determine what the actual physiological effect of the plan might be. Recently, however, De la Tourette and Chipault have published in the *Gazette des Hôpitaux* (Nos. 49, 51, and 52) a research entitled "True Elongation of the Spinal Cord, and its Application to Locomotor Ataxia; with Experimental and Therapeutic Researches." Their experiments on the cadaver failed to show that actual elongation of the spinal cord took place during suspension. Thus they state that though the spinal column may be stretched one centimeter the cord is entirely unaffected, and they believe that in the living subject whose vertebral muscles are active even this elongation of the spine fails to take place.

Their other conclusions have been well summarized by Montgomery in the *Medical Chronicle* of Manchester. The first experiments, made on the spine alone, showed that the anterior wall of the canal was elongated by *flexion* to an extent varying from 3.1 to 4.3 centimeters—about one-twentieth of the whole length of the column. The various segments of the column were very differently affected. Thus, in the first subject, the whole elongation of 3.1 centimeters was divided up into eight millimeters for the cervical vertebrae, four millimeters for the upper ten dorsal, twelve millimeters for the next five vertebrae, and seven millimeters for the four last.

These figures for the other two subjects were, for a total elongation of 3.5 centimeters, respectively six, six, fifteen, and fifteen millimeters; and for a total elongation of 4.3

centimeters, ten, six, fifteen, and twelve millimeters.

Passing next to the cord itself, the elongation measured outside the unopened dura was, in the first experiment, 1.7 centimeters. It seemed, however, preferable to expose the cord directly to measurement; and, when this was done, five experiments were made, with the following results:

1. The total elongation of the intradural nervous elements was, respectively, 1.3, 1.6, 2, and 1.1 centimeters.

2. This total elongation was divided between the cord itself and the cauda equina, as follows:

Total elongation.		Cord.	Cauda equina.
1.....	1.3 cm.	7 mm.	6 mm.
2.....	1.2 cm.	7 mm.	5 mm.
3.....	1.6 cm.	9 mm.	7 mm.
4.....	2.0 cm.	9 mm.	1.1 cm.
5.....	1.1 cm.	7 mm.	4 mm.

It is thus seen that while the cord elongation proper is fairly constant, that of the cauda equina varies noticeably in different subjects.

3. The various segments of the cord are differently affected. The maximum elongation was of the region between the twelfth dorsal and first lumbar nerves.

From their anatomical experiments the authors conclude that "while suspension of the spine produces merely insignificant elongation of the cord, flexion, on the other hand, in a subject with the knees extended, lengthens it by about one centimeter, almost all the effect being on the posterior half in the region of the first lumbar nerves."

*Application of these Experiments in the Treatment of Locomotor Ataxia.*—In brief, the patient is placed in the sitting posture on a narrow table, the pelvis fixed, and the legs strapped down in the extended position. By means of a collar attached to the neck and shoulders any required amount of flexion of the body is produced by a cord and pulley.

In the majority of cases the force used, as measured by a dynamometer, varied between sixty and eighty kilogrammeters. The maximum is, however, never employed at first. The sensation becomes, after a very short period, acutely painful, but after a few applications the patient is able to bear the operation comfortably. The sitting should not last more than eight to ten minutes, and both the flexion and its relaxation should be most gradual.

The results obtained by the method thus described must be compared with those of suspension.

Generally speaking, the suspension treatment in selected cases caused decided amelioration of symptoms in from twenty to twenty-five per cent.; in thirty to thirty-five per cent. the improvement was slight; while in thirty-five to forty per cent. there was no benefit noted.

These were the results obtained under Charcot's direction in the Salpêtrière from 1888 to 1890. But soon after this latter date the method passed into disfavor.

By flexion forty-seven cases—thirty-nine males and eight females—were treated. Naturally the cases were selected, both this and the suspension process being contraindicated in very slowly progressing, very acute, or very late cases. Those best suited for treatment are the sufferers from lightning pains, visceral crises, anesthesia, and bladder trouble, the other signs of disease being not very pronounced. Of the forty-seven selected cases, twenty-two were very much improved in all their symptoms, and more especially as regards incoordination, pains, crises, anesthesia, and retention of urine. For some reason incontinence was not so favorably influenced.

Fifteen other cases were benefited, but the improvement was limited to one or two symptoms alone.

Ten cases—less than twenty-five per cent.—showed no improvement, in contrast to the thirty-five to forty per cent. of recorded failures after suspension.

None of this series of cases underwent less than fifteen or twenty seances. In general, the treatment should not be prolonged for more than three or four months.

#### THE TREATMENT OF IDIOPATHIC SALIVATION.

Idiopathic salivation is certainly rarely met with by the general practitioner, and even excessive ptyalism due to the ingestion of drugs is at this day not of frequent occurrence, chiefly because the mercurial preparations are more carefully administered and physicians usually give instructions and prescribe mouth-washes which tend to prevent this distressing complication of the treatment of syphilis. Now and again, however, the physician's therapeutic resources are tested to the utmost when he comes face to face with what has been called idiopathic salivation as it occurs in childhood. In these cases a careful examination of the mouth will fail to reveal any inflammation or indication of the presence of stomatitis, yet the

patient will be a great annoyance both to himself and to his care-takers by reason of the constant dribbling of saliva from his mouth, which wets his clothes and even produces by constant maceration an eczematous condition of the skin of his chest. In a case which has recently been reported by Dr. Jordan in the *Birmingham Medical Review* it is stated that the child had always dribbled saliva freely, particularly when cutting his teeth. The dribbling continued at night so that the pillow was wet, although the saliva was not as profusely secreted as in the daytime. Excepting for this one symptom the patient seemed to be in perfect health. The teeth were cut normally, but the first molars at the time the child was seen were undergoing decay. Other children in the family had no such tendency towards salivation. The patient was four years of age. Another case, a boy aged two and a half years, was brought to Dr. Jordan with exactly the same symptoms and the history that he had commenced to dribble during teething and had never ceased. His teeth were in a healthy state, but his tonsils were somewhat hypertrophied. No other lesion was found.

Jordan points out that this somewhat rare condition has been reported by other clinicians. Thus Finlayson has reported a case, and Bohn in an article in Gerhard's *Handbuch der Kinderkrankheiten* asserts that the salivation usually has its origin at the age of three or four months, or with dentition, and usually continues until dentition ceases. He refers to cases occurring in children of from two to eight years who were otherwise healthy. In most instances the condition ceases during the night, and in one instance it only appeared when the entire attention of the child was absorbed by something of interest. Although iron benefited some of Bohn's cases which were anemic, he does not think that the condition depended upon anemia, but was rather an evidence of a neurosis. The treatment which Jordan instituted consisted in the administration of full doses of belladonna administered persistently for a period of five months, until at the end of that period the child was taking as much as twenty minims of the tincture of belladonna three times a day. At this time the salivation was, as he expresses it, in undisturbed progress. In the other cases, in which the treatment by belladonna was used, there were no definite conclusions as to the value of the drug reached. In Finlayson's case, where

the discharge of saliva reached about thirty ounces in twenty-four hours, belladonna was used and the child was cured in about a month.

We have called attention to this subject because we have known of at least one case in which the administration of ten grains of camphoric acid given once or twice a day, in capsule, gave great relief. A medical friend who had tried almost every remedy commonly considered as antisecretive, appealed to us to suggest something which might be of benefit to his patient, and on camphoric acid being tried the condition was very promptly brought under control.

---

#### THE BENEFITS OF ANTAGONISTIC ACTIONS OF MEDICINES.

---

To the physician of fifty years ago, who based his therapeutic efforts upon empiricism alone and was entirely devoid of any information regarding the physiological effects of drugs upon separate and healthy organs, much of the advantage now in the hands of his modern followers was impossible. The strides made by pharmacologists during more recent times, and extending over a sufficient number of years to be worthy of confidence, have added to the results of bedside experience complete and reliable experimental facts, and have explained why and how this or that remedy causes certain effects when administered. Thus the slow pulse due to digitalis we know to be due to stimulation of the vagi, and we can use this drug with direct benefit in those cases where we have reason to believe that the inhibitory nerves of the heart are not sufficiently active. Again, we recognize the fact that strychnine is contra-indicated in conditions of acute irritation of the spinal apparatus, because it eventually stimulates this part of the nervous system, and for this very reason we use it when we believe the spinal cord to be in need of stimulation.

A knowledge of the action of drugs on particular organs also aids us in combining them in such a manner as to accomplish definite results in one organ without interfering with the functions of others, because in respect to others their effects are antagonistic. Thus in cases of cardiac irritability the use of digitalis in small doses quiets the heart by its effect on the vagi, while the addition of a little aconite prevents the digitalis from overstimulating the heart muscle itself.

In other instances where it is desirable to get the full diuretic or cardiac effect of caffeine, and full doses of the drug are needed to produce such an influence, the coincident nervous and mental excitement can be put aside by the use of bromide of sodium, which, though it quiets the nervous system, has no effect on the heart or kidneys.

Our attention has been called with renewed interest to this subject by a valuable laboratory and clinical research recently published in the *Journal of Physiology* by C. R. Marshall upon the "Antagonistic Action of Digitalis and the Members of the Nitrite Group." After reviewing the various standard researches which have been made upon these remedial substances, he proceeds to his study and finds that in practically all cases the nitrites can be relied upon to reduce or prevent any tendency to high arterial pressure induced by digitalis. This supports the clinical fact already well known that a nitrite and digitalis can be combined in cases of high arterial pressure with great advantage. Marshall's research also shows even more conclusively that though the nitrites prevent the high tension of digitalis, the latter drug does not possess a similar degree of power in overcoming arterial relaxation or lowered tension when it is produced by a member of the nitrite group.

Similar instances of the advantage of combining drugs for antagonistic purposes might be cited, but these are sufficient for our purpose. A recollection of the particular selective affinity of drugs for certain organs and their antagonisms, and the practical application of such recollections, will often greatly benefit the patient and prevent him from suffering from disagreeable effects of remedies which necessarily ensue when a single drug is given, for scarcely any drug exists but exerts an action on more than one organ of the body.

#### THE PREVENTION OF CINCHONISM.

In a number of issues of the THERAPEUTIC GAZETTE within the last few years we have referred to the untoward effects produced by various drugs, and have called attention in particular to the disagreeable after-effects which often ensue when quinine is administered. With the more moderate of these effects nearly every one is familiar, for the laity often prescribe quinine for themselves in such large doses that they speedily experience the tinnitus, or deafness and headache,

which full doses of this drug so readily produce. There are two ways in which these disagreeable symptoms may to a certain extent be modified by combining with the quinine other remedies. The oldest way, and the method which is perhaps resorted to most frequently, is the administration with each dose of quinine of five or ten grains of bromide of potassium or bromide of sodium, which seem, to a considerable extent, to modify the aural symptoms which we have mentioned. If the dose has been a very large one and the patient is particularly susceptible to quinine, it may be well to give at the same time with the quinine a little fluid extract of ergot for its tonic effect upon the cerebral and meningeal blood-vessels. Another method for the prevention of cinchonism is that which has been suggested by Aubert within the last few months. He asserts that the administration of atropine in the dose of  $\frac{1}{16}$  to  $\frac{1}{8}$  of a grain with each dose of quinine greatly modifies the symptoms, and in those cases where the quinine was given for the relief of the neuralgia aided the quinine very materially in relieving the pain. It must be remembered, on the other hand, that in those who have a susceptibility to atropine, the dryness of the mouth and throat and the disordered vision which may ensue after this dose of the drug might prove more uncomfortable to the patient than if the quinine had been administered alone.

#### THE VALUE OF ANTIDIPHThERIC SERUM IN DISEASES NOT DUE TO THE KLEBS-LOEFFLER BACILLUS.

While it is probably true that in antidiphtheritic serum we possess what is practically a specific in the treatment of true diphtheria, provided it is administered before the disease has produced so much destruction of vital organs that recovery is impossible, it would also appear from recently published statements of medical clinicians that it can be used in other cases than those which are suffering from this specific infection; and within the last month two papers indicating that antidiphtheritic serum has a wider application than we have been wont to accord it have appeared. One of these is by Revilliod in the *Revue Médicale de la Suisse Romande* of November 20, 1897, an abstract of which we publish in our Progress columns, and the other is in the *British Medical Journal* of December 11, 1897, published by Dr.

H. A. McCallum, the professor of physiology in the Western University, of London, Canada.

In the first of these papers the author argues that the increased secretion seen after the injection of serum from all the mucous membranes and other clinical facts in regard to its physiological action led him to employ antidiphtheritic serum in the treatment of asthma, and he believes that both the iodides and the serum do good by eliminating from the body of asthmatics certain noxious substances which produce the attacks. In other words, the antitoxin of diphtheria is used, under these circumstances, not on account of any supposed antitoxic property, but rather because of its power of increasing secretion and eliminating poisons from the body. In one case the patient had asthma for six years, yet marked amelioration followed the first injection, and after ten injections made during five months the patient was completely cured. In McCallum's paper, which is made in the nature of a preliminary report, he states that the serum cleanses the tongue of typhoid patients, lessens the constipation, and increases biliary secretion, and that it increases urinary flow, improves the action of the heart and the tone of the blood-vessels markedly, increases leucocytosis and the coagulation of the blood. We refer our readers to the abstracts from these papers which we publish in the Progress columns.

*RUPTURES OF THE VISCERA AND THEIR  
RELATION TO SURGICAL SHOCK.*

---

Dwight in the *Boston Medical and Surgical Journal* of August 19 and 26, 1897, calls attention to the fact that fatal shock following trauma is nearly always the result of gross, often extensive, visceral lesions, as demonstrated in his exceptionally wide experience in post-mortem examinations. He holds that visceral ruptures are far more common than is generally supposed, and that pronounced constitutional symptoms so often attributed to nervous perturbation are due either to hemorrhage or to other direct or indirect effects of such lesions. In the records of the Boston City Hospital for the last fifteen years he has collected seventy-nine cases of abdominal injuries in which the diagnosis of rupture was not made and in which no definite lesion was found to account for the symptoms which were present. Of these

sixteen died. Shock was pronounced in forty-nine of the cases. Tenderness on deep pressure persisting for from four to sixteen days was noted in thirty-nine, and in the same number there was persistent vomiting. As showing how often the amount of injury inflicted is much greater than is at first apparent, Dwight notes that of 511 cases of fractured ribs forty died, twenty-nine within three days. As a result of nine autopsies it was found that three died from hemorrhage, three from rupture of the lung, and three from rupture of the liver and spleen.

The diagnosis of visceral rupture is rendered difficult by the fact that the traumatism which produces them is less likely to cause external signs. Dwight has encountered most frequently rupture of the liver. Death is usually due to primary hemorrhage. It is extremely difficult to make the diagnosis. Rupture of the kidneys is much commoner than is taught in the text-books. The diagnosis is dependent in part upon the appearance of blood in the urine, although the absence of this sign would not exclude the injury. Many of these cases recover, others result in lumbar abscess. Exceptionally peritonitis may result from rupture of the overlying peritoneum. Rupture of the spleen was comparatively rare in the author's cases. Death is likely to ensue from primary hemorrhage or from secondary subdiaphragmatic abscess. The pancreas is from its position rarely involved. Intestinal ruptures usually occur in the jejunum or ileum. Death may result from hemorrhage, but is usually due to peritonitis. Rupture of the stomach is less common and more rapidly fatal, often from hemorrhage. Rupture of the lungs may occur without injury to the ribs and without signs of external violence. Contusions of the lung substance or hemorrhage into it are common, and in extreme cases one or more lobes may be completely macerated. These injuries when serious are commonly associated with injuries to one or more organs. The heart ruptures mostly occur in the right ventricle.

Dwight, among his conclusions, states that the lesions of various organs in all their degrees of severity have one result which they present to a greater or less degree in common—that is, hemorrhage—and that death in all cases, except in those which—like the intestines, bladder, and heart—may result fatally in a way peculiar to themselves, comes as a result of that hemorrhage. Shock to a greater or less extent is present in nearly

every case after these common accidents, which not infrequently will result in ruptures of the viscera. If it be true that in no considerable number of cases the group of symptoms commonly described by the word shock is due to hemorrhage, it is of the greatest importance that such patients should be treated for concealed hemorrhage and not for shock.

Nearly every hospital surgeon of large experience will agree with Dwight that severe shock following traumatism is a certain indication of visceral lesion. None the less it is quite certain that pronounced, even fatal, shock may develop in the absence of demonstrable lesions, though this must be regarded as most exceptional. Moreover, there are a sufficient number of cases reported, and it is the occasional experience of nearly every surgeon, to show that rupture of the viscera may occur with but slight degree of shock and that the hemorrhage resulting may be of so little moment as not materially to influence the ultimate outcome of the case. This also may be regarded as exceptional, though not so rare as the cases of fatal shock without demonstrable lesion. It is certainly true that a rapidly deepening shock following trauma to the body without external injury is usually due to visceral lesion and consequent hemorrhage, and provided the injury has been such as is likely to cause visceral rupture the constitutional symptoms might be sufficiently indicative to justify surgical interference.

Surgical intervention practised under such circumstances is likely to be successful in a very small percentage of cases, and undoubtedly hastens the fatal issue when no conditions are found which can be mechanically remedied. None the less it is probable that were, for instance, cases of abdominal contusion which had been followed by agonizing pain and deepening shock subject to a rapid exploratory celiotomy, the ultimate mortality would be much less than is the case with purely conservative treatment. Under such circumstances during operation the patient should receive the appropriate treatment for profound shock, and the operation, if this is possible, should be conducted upon a hot water bed and with the temperature of the operating room above 80°. The remedies most likely to be serviceable are strychnine in full doses and subcutaneous or intravenous injections of normal saline solution when it is evident that a large quantity of blood has been lost. It should be remembered that the quantity of saline used is not definite, but

that it is slowly injected until the pulse regains its volume. This may require over three pints. The intra-abdominal manipulations should, of course, be performed as rapidly as practicable, and subsequently inhalations of oxygen or even artificial respiration may be required for many hours.

---

## Reports on Therapeutic Progress

---

### *ORTHOFORM, A NEW LOCAL ANALGESIC.*

It has been found by Dr. EINHORN and Dr. HEINTZ, of Munich, that the compound methylic ether of amidoxybenzoic acid is possessed of remarkable anesthetic, or rather analgesic, properties when locally applied. To this substance the name of "orthoform" has been given. It is a white crystalline powder without taste or smell, and it dissolves slowly in water. Unlike cocaine it is non-poisonous, and though its analgesic action is somewhat tardy in showing itself, it is very much more persistent than that of the older drug. This prolonged effect is very valuable in the case of painful sores or wounds, more especially in burns and in fissures of the lips or nipples. It may be applied to mucous membranes in powder or as an ointment. Orthoform diminishes the secretions and is antiseptic. Its local action may be taken advantage of for internal administration in painful ulcers of the stomach, whether these are or are not of a malignant nature. The hydrochlorate, which is very soluble, is too acid for use as a hypodermic injection or for applying to the eye, but may be employed for internal administration or for urethral injections. In a case of gleet a ten-per-cent. solution was well borne and gave relief from pain for many hours, but it provoked severe reaction in a case of acute gonorrhea—here, however, the discharge ceased completely in four days. As to the dose, a saturated solution of orthoform in water at ordinary temperature is suitable for local application, and seven and a half grains of the hydrochlorate, or even more, may be given internally several times a day without any inconvenience. It appears, therefore, that this substance and its salt may be considered entirely non-poisonous. Indeed, in a case of carcinoma of the face more than 700 grains was locally applied during the course of a week without any injurious effect, great relief being obtained.—*The Lancet*, Sept. 18, 1897.

**STREPTOCOCCIC INFECTION AND MARMOREK'S SERUM.**

In a bibliographical article on this topic published in the *Journal of the American Medical Association* of September 11, 1897, GEORGE W. COX goes over much of the evidence concerning the value of antistreptococcic serum, and in concluding refers to the use of Marmorek's serum in cases of tuberculosis. He points out that a little more than a year ago Dr. Chas. T. McClintock, of Ann Arbor, read a paper before the Michigan State Medical Society in which he predicted that the antistreptococcic serum would find its greatest usefulness in cases of tuberculosis. That was the first published utterance to this effect, and Dr. McClintock has proved himself a prophet. During the month of July, 1896, Dr. W. H. Weaver, of Chicago, used Marmorek's serum in three such cases, reporting them in the *Journal of the American Medical Association* of September 5, 1896. That was the first published report of cases treated in this way. Since that time a number of cases have been so treated by physicians in different parts of the country, but little or nothing has been published concerning them—why, it would be difficult to say. The importance of the subject would seem to merit more attention than it has received. In all the published reports, however, and in all received from private sources, there has been a pleasing unanimity on the action of the serum. Without exception it has done all that was expected of it; that is to say, it has invariably destroyed the streptococcus microbe and thus freed the case from a disagreeable and dangerous complication. Having thus converted the case from one of mixed infection into one of simple tuberculosis, the system is left in better condition to resist the ravages of the tubercle bacillus, and consequently is more likely to respond to appropriate treatment for the destruction of this germ. The serum should be used in those cases only where the bacteriologic test shows the presence of the streptococcus microbe. In all such cases there is liable to be considerable cough, purulent expectoration, night sweats, high temperature, insomnia and anorexia, all of which are greatly modified and sometimes disappear altogether under the influence of the antistreptococcic serum. Oftentimes the train of symptoms just enumerated will be found where there is no streptococcic infection. These, as a rule, are very grave cases, and the serum treatment is not indicated. Lack of space

forbids a detailed account of the progress of the different cases in which the serum has been used; but suffice to say that while some of them were hopeless as far as ultimate recovery was concerned, yet without exception there was such decided amelioration of distressing symptoms as to lead to the conclusion that earlier employment of the serum would at least have resulted in greatly prolonging life.

Marmorek's serum should always be used by hypodermic injection into the cellular tissue. If due antiseptic precautions are observed and ordinary skill used in its administration, it is free from danger, and the dose is practically without limit.

In all grave cases, such as puerperal septicemia, and especially if treatment has been considerably delayed, an initial dose of thirty cubic centimeters is advised; this may be followed by doses of ten cubic centimeters or twenty cubic centimeters every twelve or twenty-four hours, according to the symptoms.

In ordinary cases of erysipelas the initial dose is twenty cubic centimeters, and in many instances may be all that is required. However, it may be repeated once or twice in twenty-four hours if necessary. In the complications of diphtheria and scarlet fever one dose of ten cubic centimeters will be found sufficient in the vast majority of cases. In the mixed infection of tuberculosis the dose should ordinarily be ten cubic centimeters, to be repeated every second or third day until the microbes have disappeared from the sputum, usually requiring from four to six injections.

In all other affections, such as acute abscesses, pelvic inflammations, chronic inflammation of the middle ear, and in suppurative processes generally where the streptococcus germ is found, the dose must be regulated according to the exigencies of the case.

Children bear the serum remarkably well, and ten cubic centimeters is the usual dose for children of all ages.

Almost any part of the body where the skin is not tightly drawn may be selected for the injections. In adults preference has usually been given to the lumbar or gluteal regions, while in children the lower abdomen, a little to the right or left of the median line, is more frequently selected. A perfectly sterile syringe and needle should be used; and unless some special condition exists to call for more thorough cleansing, the site may be sufficiently prepared by a careful bathing in alcohol.

The author draws the following conclusions from the use of the serum: (1) In Marmorek's serum we have a remedy of the greatest therapeutic value; (2) so far as known, it is only applicable to streptococcal infection, simple or mixed; hence it naturally follows that: (3) an early bacteriologic examination should be made in order to settle the question of diagnosis and point the treatment; (4) its action upon the microbe is rapid and certain if given in adequate doses.

#### DRUGS WHICH SHOULD NOT BE EMPLOYED DURING PREGNANCY.

In an article on this subject in the *Journal des Praticiens* of August 28, 1897, M. BOISSARD remarks that in a general way all therapeutical intervention should be forbidden when it is followed by abortion or premature labor. Emmenagogues, he thinks, should be banished from the treatment, not only of pregnant women, but in the case of those in whom there is a suspicion of the possibility of the beginning of pregnancy.

According to him there are no abortive drugs in the strict sense of the word, but there are drugs which given in toxic doses may cause at the same time both abortion and the death of the woman; these drugs are therefore useless and inefficacious, and there is danger of poisoning to the woman. With regard to the ecboic and oxytocic drugs, they belong to another class, and have the property of arousing and aiding the progress of uterine contractility or of strengthening the intensity of the uterine contractions after they have been aroused; the action of the latter is certain, that of the former doubtful.

The action of quinine sulphate and of sodium salicylate is not to provoke abortion or premature labor, says M. Boissard; that would be very much to be regretted, as obstetrical therapeutics would be deprived of two valuable drugs. Drugs that have that property may, however, be advantageously employed in cases of contraction of the pelvis, in which it is expressly indicated to interrupt the course of pregnancy.

The abortive or ecboic action of quinine sulphate, says the author, has been discussed by many writers, whose investigations and experiments show that this drug should not be considered as an abortive agent; in several cases in which there was contraction of the pelvis and it was necessary to interrupt the pregnancy, this drug was given every day in large doses without producing the least

symptom of labor, yet it was given in amounts that, if not toxic, were at least sufficient to cause quinine intoxication. M. Boissard thinks that there should be no hesitation in employing quinine sulphate during pregnancy whenever symptoms of malarial infection manifest themselves, and these cases are rather frequent, pregnancy serving to arouse in some way the previously dormant infection. It is the same way with sodium salicylate; only ergot, because of its oxytocic properties, should be rejected, even in cases of hemorrhages during pregnancy, in order not to cause tetanization of the uterine fibers.

Narcotic, analgetic or anesthetic drugs may be administered without fear, when their employment is justified, and may be of great benefit to the parturient woman. The different preparations of belladonna and of stramonium may be employed, also antipyrin, opium, chloral, and chloroform or ether. In cases of threatening abortion laudanum is admirably borne, and as much as a hundred drops in enemata of boiled water may be given during the twenty-four hours, twenty-five drops at a time being the amount used. This is true also of chloral in vomiting, and of chloroform, which is employed during pregnancy to clear up the diagnosis and ascertain the exact configuration of the pelvic cavity, in order to reduce retroversion of the gravid uterus, and to facilitate version by external means. The different mercurial preparations, continues M. Boissard, are administered only in acknowledged cases when the physician finds himself in the presence of a series of abortions or premature births of macerated infants.

Concerning the administration of purgatives, M. Boissard says that under the pretext that in the beginning of pregnancy it is dangerous to use purgatives, some women reach an extraordinary condition of constipation which is much graver than the possibility of the danger they fear. In a general way it is of great advantage to keep the functions of the intestine in a good, regular condition by the use of castor oil, cascara, senna, and enemata of boiled water.

With regard to bathing, this favors the functions of all organs, and particularly of the skin, and pregnant women may and should take baths during pregnancy, one every fifteen or twenty days at the least, observing the following precautions: Not to bathe at a time corresponding to the last appearance of menstruation; not to allow the tempera-

ture of the bath to be above 96.4° F.; not to remain in the bath longer than fifteen minutes, and to guard against taking cold on coming out of it.

Concerning vaginal injections, the author is in favor of their general use and thinks the necessity of their employment should be explained to women. Some precautions are given in regard to their use, and the author adds that if they are observed accidents resulting from the action of the hot water on the uterine fibers will be avoided, also any traumatism to the neck of the uterus.—*New York Medical Journal*, Sept. 25, 1897.

#### IODOFORM SUBSTITUTES.

Iodoform contains about twenty-nine parts of pure iodine in thirty. Its antiseptic and deodorizing effect is therefore due to this element; the carbon and hydrogen with which it is associated render the iodine non-irritant, either when taken by the mouth or applied topically. A great disadvantage attending the use of iodoform is its disagreeable odor. It is impossible to entirely mask this odor, although it may be covered to a great extent by mixing it with various aromatic substances, such as balsam of Peru, Tonquin bean, coumarin, menthol, thymol, oil of sassafras, attar of roses, oil of peppermint, oil of anise, oil of eucalyptus, carbolic acid, etc. A number of iodoform substitutes have been introduced, some containing iodine, and hence supposed to act like iodoform, and others with no iodine in their composition, but which have a similar action to iodoform. Many of these substitutes are proprietary articles of German origin. The results of inquiries made at hospitals, of pharmacists, and wholesale chemists and druggists, show that these iodoform substitutes have in no way diminished the use of iodoform, and that, in fact, they are in very small demand.

Iodol (tetra-iodo-pyrrol) stands at the head of the list of iodoform substitutes as regards the amount of iodine present. It contains about twenty-seven parts in thirty. Iodol is obtained by precipitating pyrrol with iodoiodate of potassium. It is a micro-crystalline, brownish-white powder, having a faint thyme-like smell, and is soluble in six parts of absolute alcohol, but nearly insoluble in water. It is said to produce no toxic action like iodoform when wounds are dressed with it, and its application is painless. Iodol has been used with good results in granular and chronic conjunctivitis, hard and soft chan-

crees, and various ulcers much improve under its use. It possesses some anesthetic action, and acts as an astringent when discharge is copious.

Losophan (meta-tri-iodo-cresol) contains twenty-four parts of pure iodine in thirty. It is a grayish crystalline powder, soluble in alcohol, chloroform, oils, and fats. It has been found useful in parasite skin affections, but not of general value, and it is apt to cause irritation.

Iodo-salicylic acid and di-iodo-salicylic acid are iodine compounds of salicylic acid in which one or two atoms of hydrogen respectively are replaced by iodine. Di-iodo-salicylic acid contains twenty parts of iodine in thirty, iodo-salicylic acid fifteen in thirty. These compounds are powerful antiseptics. They possess the combined action of iodine and salicylic acid, and have been successful in the treatment of acute polyarticular rheumatism where salicylates have failed. These acids are in the form of white micro-crystalline powders, slightly soluble in water, soluble in alcohol, ether, fixed oils, and like salicylic acid, also in collodion.

Soziodol (di-iodo-para-phenolsulphonic acid) is composed of fifty-four per cent. iodine, seven per cent. sulphur, and twenty per cent. phenol. It has been combined with sodium, potassium, ammonium, lead, mercury, and zinc, which have been suggested as odorless substitutes for iodoform. The sodium salt which has been used is in colorless shining acicular crystals, soluble in water. The salt is well tolerated as an external application. It has been given internally in doses of twenty grains three times a day. Soziodol has been found useful in the treatment of whooping-cough—three grains blown into each nostril once daily. A solution of soziodol-mercury with iodide of sodium has been recommended for intramuscular injection in syphilis.

Aristol (di-thymol-iodide) is a reddish-brown powder containing 45.8 per cent. of iodine. It is insoluble in water, glycerin, or alcohol, but soluble in ether or oils. It has been used successfully in various skin affections, psoriasis, eczema, rhinitis, ozena, and lupus, but has proved unsatisfactory in lichen rubra, soft chancre, and gonorrhea. Aristol has a certain effect on venereal ulcers, but acts very slowly; the only advantage it possesses over iodoform is absence of smell—its activity is inferior. It has been found of service in the first and second stages of pulmonary tuberculosis when no cavities exist. It also

lessens cough and night sweats. Burns and scalds have been successfully treated with aristol, and the application in a powder to the cornea in keratitis and in an ointment in corneal ulcers has given good results. It is of great value in nasal affections; it lessens the discharge, relieves pain, and stops bleeding when used as an insufflation in cancer of cervix uteri.

Euophen (iso-butyl-ortho-cresyl-iodide) occurs as a pale orange, non-crystalline powder, containing twenty-eight per cent. of iodine. It possesses powerful antiseptic properties, and being resinous to the touch it adheres well to mucous membrane and wound surface, and does not easily cake. A given weight as compared with iodoform will cover a surface five times the area of the latter. It is non-poisonous, and acts only when brought into contact with secreting surfaces, which decompose it and liberate iodine. Its lightness and freedom from odor make it especially useful in dentistry. The general opinion of euophen is that it may be used with advantage in all cases where iodoform has been used. Improvement has followed its use by inunction and subcutaneous injection in tubercular leprosy, and it has been found serviceable in eye diseases, otitis, and ozena. Euophen has failed in eczema, psoriasis, and gonorrhea, but has given satisfactory results in simple and venereal ulcers, and in oily solution injected daily for syphilis.

Loretin (meta-iodo-ortho-oxy-chinolin-ana-sulphonic acid) is a bright yellow crystalline powder, odorless, and similar in appearance to iodoform. It is very slightly soluble in water or alcohol, and insoluble in ether, but forms soluble salts with alkalis, except with lime. It is non-poisonous and unirritating, and has been used with marked curative effect on burns, ulcers, and other wounds.

Airol, a gallate of bismuth and iodine, is a light grayish-green powder, stable in dry air, but when left in contact with moisture iodine is gradually liberated. It is insoluble in water, alcohol, and ether. Airol is astringent and desiccative, as well as being antiseptic.

Di-iodoform (ethylene periodide) occurs in yellow crystals, almost inodorous, insoluble in water, soluble in chloroform, and slightly in alcohol and ether. It is partly decomposed by light. It has been recommended as an antiseptic in place of iodoform.

Antiseptol (iodosulphate of cinchonine) is an odorous brown powder, which has been recommended as a substitute for iodoform. It contains half its weight of iodine, and is

soluble in alcohol or chloroform, but is insoluble in water.

The chief non-iodine compounds which have been introduced to compete with iodoform as an antiseptic are dermatol, thioform, and thioresorcin.

Dermatol as a basic gallate of bismuth is recommended as a powerful non-irritant antiseptic and desiccant. Applied to wounds it induces rapid cicatrization, does not irritate nor give rise to toxic effects. It is not well suited to septic wounds, and insufficiently stimulating in chronic indolent ulcers. It is a quicker microbicide than iodoform. Its use in the treatment of venereal ulcers has been successful, and also in pustular and diphtherial conjunctivitis, corneal ulcers and pannus, but of little use in blepharitis. Dermatol is a yellow powder, odorless, and insoluble in water.

Thioform, a basic bismuth salt of di-thio-salicylic acid, is a yellowish-brown powder, odorless, and insoluble in water. Its claim to supplant iodoform is based upon its freedom both from odor and from toxic properties, its greater antiseptic strength, and its desiccative action. It freely absorbs secretions from wounds without forming a crust. As a desiccant antiseptic, especially for eye cases, it has been recommended.

Thioresorcin is a combination of sulphur with resorcin. It is a yellowish-white, inodorous and non-toxic powder, insoluble in water, slightly so in alcohol and ether. As a dusting powder it has been used instead of iodoform, and a ten- to twenty-per-cent. ointment for eczema, psoriasis, and other skin diseases.—*British Medical Journal*, Sept. 18, 1897.

#### A FURTHER REPORT ON THE TREATMENT OF TUBERCULOSIS BY IODOFORM INUNCTIONS.

Dr. LAWRENCE FLICK, who is well known as an enthusiastic student of tuberculosis from a clinical standpoint, makes a report upon his favorite method of treating pulmonary tuberculosis in the *Journal of the American Medical Association* of July 31, 1897.

The conclusions that the author believes himself justified in drawing from his eight years' experience in the treatment of tuberculosis with iodoform and euophen are:

1. That incipient cases can almost always be cured by euophen or iodoform inunctions.
2. That cases advanced to the breaking-down stage may be improved very much by

this method of treatment and can sometimes be cured.

3. That the treatment ought to be continued even after acute symptoms have disappeared, and it should be maintained until perfect health is reestablished.

As to the respective merits of euophen and iodoform, from a therapeutic point of view, both have apparently done equally well in the author's hands as far as the results are concerned. From an esthetic point of view, the euophen is much to be preferred because it is much less offensive in odor, and can be almost perfectly disguised. He has for almost a year discarded the use of iodoform. The formula which he now employs is as follows:

Euophen, 1 drachm;  
Oil of rose, 1 drop;  
Oil of anise, 1 drachm;  
Olive oil, 2½ ounces.

This makes an excellent preparation, giving a perfect solution, and being in no wise offensive to the sense of smell. He instructs his patients to rub about a tablespoonful thoroughly into the inside of the thighs and into the armpits before retiring at night, and if they have any fear of odor, to sponge themselves with bay rum or bath whiskey when rising in the morning. By following these instructions the most fastidious can satisfy themselves that they will not attract attention in public. The treatment is somewhat troublesome, but patients when they once discover that they are deriving benefit from it not only do not object to its use, but are anxious to employ it. He has had very little trouble on the score of getting patients to persevere with the treatment during the acute or subacute stages of their illness, but only when they have apparently recovered their health. Most people settle for themselves the question whether or not they are well, and the author finds that when consumptives begin to enjoy a fair state of health they do not care to any longer submit to a troublesome treatment.

It is but proper for Flick to say, further, that the majority of cases that he has treated in this way and upon which he bases this report were among the poor and never had the advantage of climate, or even temporary removal from the city. Indeed, many of them did not even have the home comforts and the advantages in food which are so important in the treatment of tuberculosis. The results ought therefore to be judged upon a basis of unfavorable environments,

for which reasons, in comparison with other results, some allowance ought to be made. He has no doubt that in sanatoria favorably located much better results could be obtained by this treatment.

The author has long since been convinced that it is the iodine which gives the good results, and that the advantages of using euophen or iodoform through the skin lies in the fact that an even and continuous influence can be maintained on the blood by the gradual absorption of the drugs and giving off of the iodine in the blood or tissues. He confesses that he has arrived at these views largely by exclusion, because they are the only ones tenable with our present knowledge of the etiology and pathology of tuberculosis. When tuberculosis has once advanced beyond the first stage it is only curable by the establishment of an immunity against any new colonies of the tubercle bacillus. This is because when the circulation is once cut off from the existing deposit, cure can only take place by either getting rid of that deposit, or by walling it in. Usually Nature makes an effort to get rid of the deposit through the process of degeneration and ulceration through the healthy tissues. But inasmuch as the germs have to pass through the healthy tissues when the broken-down tissues are being thrown off, reinfection is almost certain to take place unless the individual possesses an immunity which makes it impossible for the germs to again find proper soil for development. This immunity must, moreover, be constant and sufficiently permanent to maintain an uncongenial soil until all the germs have been ejected from the organism. The iodine which is given off from the euophen and iodoform into the circulation after its absorption by the skin maintains, he believes, to a certain degree, an immunity which makes new colonization difficult, and in this way contributes toward a cure.

Where tuberculosis is still incipient, and where the circulation has not yet been cut off from the nodules, he believes that the iodine when brought into the system through the euophen or iodoform inunctions will almost invariably cure. Of the cases of this description that he has treated, most have recovered, although a number had relapses and subsequently died of acute tuberculosis. Some of these cases, however, were constantly exposed to reinfection from other members of the family, and may have contracted new attacks.

It is but fair to say that an incipient case of tuberculosis is an unconfirmed case as far as diagnosis is concerned. The diagnosis in incipient cases must necessarily depend upon clinical symptoms, as there is not yet any broken-down tissue, and there is no possible way in which the tubercle bacillus can be demonstrated. The clinical symptoms of tuberculosis are, however, sufficiently striking and well enough defined to allow of a rational diagnosis. Where we have a rapid pulse, a daily rise of temperature, with impaired resonance, or partial consolidation of part of a lung with prolongation of the respiratory murmur, there can be little doubt about the nature of the disease from which the person is suffering. We know, moreover, from past experience that persons in this condition, if allowed to go on without treatment, invariably develop into full-fledged consumptives. While there is, therefore, some doubt about the diagnosis of the cases which he has quoted as incipient, they must be accepted as representative cases of their kind and must be allowed to pass as a basis for the conclusions which he has given.

Flick feels that it is proper for him to say, in conclusion, that much of the benefit which he has had in the treatment of the cases quoted in this paper was no doubt due to tonics and creosote. As indicated throughout the paper, he has used creosote in large doses in all cases advanced to the breaking-down stage. In such cases he thinks better results are obtained by using both creosote and euophen than by using either drug alone.

#### *A DISCUSSION ON THE TREATMENT OF INSOMNIA:*

An important discussion on the treatment of insomnia was carried out during the recent meeting of the British Medical Association in Montreal. Prominent physicians expressed themselves concerning the value of various therapeutic measures. Among others CLARKE stated that in the sleeplessness associated with acute mania, drug treatment is at times extremely valuable in the early stages, but his experience has been that, if marked beneficial results do not occur almost at once, they will not appear at all, and harm will result from the drug treatment. It is doubtless true that some of the hypnotics are better than others, but he is strongly impressed with the advisability of substituting other treatment when possible, such as affusions easy of application, massage, etc. With-

out drugs and by simple physical means it is easy in many cases to restore normal arterial tension and cause sleep. In the insomnia of acute mania the warm bath is oftentimes of the greatest value. Our custom is to use water at a temperature not exceeding 104° F., and this is continued for twenty minutes or more while cold applications are made to the head. The bath at 104° F. is certainly much safer than one at 110° F., as advised by some authors, and there is less danger of inducing collapse, a danger never absent in a case of mania. Of course the warm bath is contraindicated where heart failure is threatened or where organic heart trouble is present. Those who have seen excited patients actually fall asleep in the warm bath can easily believe in its advantages. Its good effects can be understood when we study the physiology of sleep, and the whole procedure is devoid of the objection which so frequently applies to drugs, namely, that the bodily functions, particularly the assimilative powers, are impaired. That this frequently occurs with the continued administration of hypnotics has been proved time and again.

The danger of collapse during and after the administration of hot baths has been referred to; but certainly it is no greater than is to be feared from even such apparently innocent drugs as trional and sulphonal. Van Schalk states that trional has no inhibitory action upon the secretions, seems to possess a stimulating effect, is well borne by the stomach, is easily absorbed by the rectum, and does not produce unpleasant after-effects. It certainly possesses many virtues, but at times is borne very badly; and a case of poisoning recently reported would go to show that even trional is not always safe. In this case twenty grains had been given daily, and as a result there were hebety, ataxia, tremor, transposition of words, psychic depression, and weakness and incontinence of urine. In the author's own experience he has seen unpleasant results follow the administration of even small doses of trional. Perhaps he has laid too much stress on sleeplessness in acute mania, but to his mind it is a very important subject and so frequently defies routine treatment. Sometimes, too, it is surprising how quickly the sleeplessness yields. Within the last few weeks he has seen persistent insomnia in a maniacal case in which there was extreme restlessness give way before nothing more complicated than rest in a hammock slung under shady trees all day long.

Sometimes the time-honored cup of hot milk at bedtime induces the sleep habit, and where a stimulant is indicated a hot toddy is oftentimes worth a dozen doses of chloral or its equivalent.

Insomnia occurring in neurasthenia is possibly one of the most difficult and unsatisfactory forms to deal with, but a study of the arterial pressure at the radial pulse will almost invariably show that in this condition the pressure is lowered. In many cases, as suggested by De Fleury, where the patient with asystole cannot sleep, it is because the arterial tension is low. If his feeble heart is strengthened by digitalis, sleep is possible. In many cases one can substitute the dynamic agents, massage, frictions, douches, and transfusions, and at the same time caffeine and digitalis can be employed as heart tonics. It is with the neurasthenic cases that the amateur doctors who exist in every community have their most satisfactory experiences in the way of suggestive lines of treatment as unique as they are absurd. In the *British Medical Journal* of September 29, 1894, we find a clipping from the *Glasgow Herald* in which one of these cures for sleeplessness is recommended. It is as follows: "Soap your head with ordinary yellow soap; rub it into the roots of the brain until it is lather all over; tie it up in a napkin, go to bed, and wash it out in the morning. Do this for a fortnight. Take no tea after 6 P.M." The *Journal* advises following the directions about the tea and leaving the instructions regarding the soap as a last resource. Insomnia is one of the diseases of civilized life and exceedingly common among the highly intellectual and brain workers. It is a condition which may be cultivated and sometimes may certainly be called a bad habit, for after all, as pointed out by A. W. McFarlane, of Glasgow, habit plays a very important part in the development of some forms of insomnia. Sleeplessness, he suggests, may arise in persons in health from bad habit alone. Nurses often suffer in this way. They sometimes curtail their sleep unduly, to find, when their services are no longer needed, they cannot sleep. Their brain cells have acquired the bad habit of maintaining activity when they ought to be reposing.

It is a simple matter to give advice to those who have acquired the sleepless habit; it is difficult for them to follow it, for sometimes the very attention that is directed to the bad habit makes it worse. We are told that a good sleep habit should be sedulously

cultivated by falling asleep without delay immediately after retiring. We cannot sleep if we continue to think, we are told. The tossing, restless one says: "Tell me how to avoid thinking when in bed, and I will follow your advice." Some men are so harassed during the day that they are driven to do their thinking in bed, but it undoubtedly means burning the candle at both ends. For these overwrought and oftentimes nervous people the author has found a glass of hot milk on retiring useful in some cases; in others half a pint of bitter ale answers every purpose. Oftentimes, too, it is necessary to arrange the patient's diet on a physiological basis. He agrees with Dr. McFarlane that regularity in the habit of retiring is of more importance than going early to bed, and certainly when one who has suffered from insomnia has succeeded in overcoming the bad sleep habit he should be slow to endanger his health and happiness by doing anything likely to induce insomnia again.

Change of air is extremely valuable, and for most people of nervous type an outing under canvas in the northern woods of Canada is a sleep producer of the most remarkable kind. The author has seen men, haunted for years by the demon insomnia, go to these woods, and while there develop a sound sleep habit which added years to their life. After the first night at camp, sleeplessness is almost unknown. Personally he prefers advising almost anything rather than drug treatment in the common forms of insomnia, and feels satisfied that we are playing with fire when we resort to the use of hypnotics, except as a temporary expedient. Of course we should not forget in these different forms of insomnia that sleeplessness is frequently something more than a bad habit; it is a symptom of other trouble, and it is necessary to discover and treat the underlying cause.

If neurasthenia is to be regarded as one of the autotoxic diseases—and there is abundant evidence to support this view—in all probability the effect will disappear with the removal of the cause. The same remarks apply to all of the cases of insomnia resulting from toxemia; and when we get clearer light on autotoxis than we have at present, no doubt it will be a simple matter to improve our method of treatment. In neurasthenia autotoxis will admirably explain the etiology of the disease, as has been pointed out by Van Giessen and others. With insomnia accompanying surgical operations the

author has had little experience, but the subject has been deemed worthy of a good deal of attention by those who have had ample opportunity to observe it.

G. G. Van Schaick concludes that insomnia, from whatever cause, is an important complication of surgical disorders. Its relief is necessary for the comfort of the patients, improves the prognosis, and naturally assists recovery after operations. Where pain is the chief factor morphine is the only drug that will relieve with certainty, although there is a strong feeling in favor of the use of trional.

In a general way, then, Clarke may say that many writers are impressed with the belief that in a majority of cases of insomnia drug treatment is to be avoided, if other more simple methods of inducing normal sleep are found successful. Certainly the simple methods should be tried before drug treatment, and in any case the condition of the arterial pressure should be carefully studied and noted, before any line of treatment is decided on.—*British Medical Journal*.

#### ON THE USE OF *SENECIO* IN DISORDERS OF MENSTRUATION.

FOTHERGILL (*Medical Chronicle*, September, 1897) in a prize research on this drug, of a clinical character, tells us that the cases in which he has employed these preparations fall into four groups, and, so far as they go, tend to provide the answers to four questions, thus:

1. In pregnant women—Does *senecio* cause abortion?
2. In amenorrhea, without pregnancy—Does *senecio* cause menstruation?
3. In persons menstruating regularly—Does *senecio* cause the flow to appear earlier than usual?
4. In dysmenorrhea—Does *senecio* relieve pain?

The results lead Fothergill to agree with Murrell that "*senecio* is not an ecboic." He also agrees with Murrell that the drug will not provoke menstruation in cases of marked anemia or advanced phthisis, but will do so in cases of functional amenorrhea. Murrell, however, thinks that *senecio* increases the quantity of the discharge, while the author's own cases point to the opposite conclusion. The views of Bardet and Bolognesi are identical with Fothergill's on these points, though he differs from their views as to the mode of action of the drug. As to dysmenorrhea, Murrell, Dalché and Heim found the

drug useful in certain cases, while the author is inclined to agree with Bardet and Bolognesi that it will not be found of much use for the relief of pain. Finally, he thinks that the pharmacology and chemistry of the plants of this genus should be worked out by competent hands, and that those interested in disorders of menstruation will find the drug worthy of a clinical trial.

[The dose of the fluid extract of *senecio* is twenty to thirty minims.—ED.]

#### PHARMACOLOGY OF *STROPHANTHUS*.

The well known pharmacologist, Dr. E. M. Houghton, contributed an interesting paper on this topic at the recent meeting of the American Medical Association. In concluding it he says: "Briefly summarizing the pharmacology of *strophanthus* we may say that its chief action is upon the nervous mechanism controlling the action of the heart, and upon the heart muscle itself, lessening pulse-rate, increasing the blood-pressure, and augmenting the work of the heart, without causing constriction of the arterioles or any special action on the vasomotor mechanism, the diuresis and other important results being due mainly to improved circulation. Its special advantages over *digitalis* may be briefly stated as follows: It does not produce gastric disturbances, and does not show cumulative action. The constriction of the vessels by *digitalis* may be a source of great danger owing to the extra strain thrown on the ventricle, especially in fatty heart. *Strophanthus* has no such tendency. It acts quicker and with greater certainty. Owing to its ready solubility it is better for hypodermic administration, and the strength of its preparations can be more easily standardized."—*Journal of the American Medical Association*, Sept. 11, 1897.

#### TREATMENT OF GOUT.

Dr. H. C. Wood has recently, in his characteristic manner, discussed this subject in the *Journal of the American Medical Association* of July 31, 1897. He says that with regard to drugs there are a great many people who tell us that salicylates do no good. Men do not get good out of salicylates because they do not use them properly. The author does not believe that salicylates cure gout or rheumatism, any more than that bromides cure epilepsy. They simply aid in keeping down the diathesis. If there be any cure, it is exercise. If we use our salicylates on a

case properly, and get no response, we have something more than ordinary gout or rheumatism to deal with. There are certain cases which approach typical gout such as we rarely see in America, in which colchicum does good, much more good than salicylates. He has seen two cases of typical English gout corresponding to Sydenham's description, and only two. We do not have it in this country. These cases colchicum suits better than salicylates do. Sometimes when the case is on the border line, we will get the best results by a combination of colchicum with salicylates. If we have a strong, robust man, he will stand it. Give him knock-down doses in addition to purging him and we will bring him through. But that treatment may be worse than the disease, and has to be used with caution.

In using salicylates the profession almost universally choose the worst salt they can find, and that is sodium salicylate. It is, perhaps, not so bad as salicylic acid, but it is much more apt to turn the stomach, and is less effective and more depressing than the other salts of salicylic acid. The two salts which are truly useful are the ammonium salt and the strontium salt. The ammonium salt acts immediately and severely; the strontium salt acts slowly. If we have an acute case, we should use salicylate of strontium or use the two combined. The strontium salt has this advantage, that it does not derange digestion anything like the other preparations, and many a time the author has seen the best effects on the intestinal condition from the use of the strontium salt.

In a large majority of cases we will find that salicylates produce depression, perhaps a little nausea, and general wretchedness, and the patient refuses them. Nine times out of ten we can overcome those effects by combining our salicylate with digitalis and strychnine in the same prescription.

As to baths, we cannot cure a diathesis by such means. But baths are useful—hot baths, steam baths, Turkish baths. Any man who values his own life, who has had a gouty grandfather, ought to take a Turkish bath once a week. We cannot wash out ancestral traces in any other way. The kidney disease and the atheroma would be far less rife if we used the hot bath more than we do. The baths eliminate, give a temporary result, and are very useful when employed with the understanding that they do not cure the disease but relieve the symptoms.

Wood then says a word about the Tallerman-Sheffield apparatus, or the use of dry heat, with which he has had a good deal of experience this year. For about three months he had a large clientele using it all day long. In the first place it is absurd to suppose that this is going to cure the gouty diathesis any more than any other application will; in the second place it is his experience that it has very little value in rheumatoid arthritis; and in the third place it is of very little value in chronic inflammations, even of purely gouty character, in joints. But the office formerly crowded with people seeking relief is empty to-day, and that is the best criterion of the result. If the results claimed for the treatment were obtainable the author says he could soon fill the hall in which he read the present paper with patients, for they all want relief, but every missionary he has sent out converted the people to the wrong faith. On the other hand, when we have deposits in the tendons and outside the joints; when we have traumatic synovitis, whether in baseball men or other persons, the results of this apparatus seem almost marvelous. He has seen a pitcher's hand drawn up and disabled for three or four years, the condition pronounced by a distinguished physician as gout, treated by the dry heat method, and after three or four treatments the hand became pliable and the use of it came back. So, in acute strains and tendinous inflammations, this dry heat is of great value. In subacute rheumatism it is of value through its sweating and local influence. It has to be used at high temperatures. Wood carried it up to 330° F. We can scorch the lint wrapped around the limb without scorching the limb. It has no value at all in old cases of rheumatoid arthritis, and is of very little use in rheumatism of the joints, according to the writer's experience.

---

*PRELIMINARY REPORT ON THE ACTION  
OF BEHRING'S SERUM IN DISEASES  
NOT DUE TO THE KLEBS-  
LOEFFLER BACILLUS.*

In the *British Medical Journal* of December 11, 1897, Dr. McCALLUM, of London, Canada, records a number of interesting facts in regard to the more general use of anti-diphtheritic serum. His paper is so suggestive that we quote it entire:

One of the intuitions that have led medical men to oppose the claims made for Behring's serum in diphtheria has been a necessary

belief in specialization of defense in mycotic disease. The physical law of conservation of energy, which is doubtless as truly a biological law, would suggest that tissue defense was general, not special; and if there be defensive proteids formed in any considerable quantities, these are but the expressed products of the vital energies of the general tissues. While the writer readily admits, as suggested by Dr. Lauder Brunton, that the proteids by the readjustment of their molecules can be specialized, yet such specialization is doubtless not permanent, and once these proteids are in the circulatory currents there is no reason to believe their usefulness is gone in defense against other diseases. On the other hand, the doctrine of tissue tolerance, while tenable for cases rendered immune by long-continued and increasing dosages, cannot be reasonably entertained for sudden change of front seen after a few doses of serum—the development of tolerance must be the work of months, not hours.

While the writer is not led afieid by a discussion on immunity, he states in passing that he believes Nature has no single function or metabolic phenomena she cannot fly to for defense in times of peril.

The first and foremost of these defensive agencies, and at the same time the most ancient, is vital movement. The differences in immunities and cures are doubtless differences in emphasis on the several factors in their accomplishment. It has occurred to the writer that no fair trial has ever been given to Behring's serum in diseases (not diphtheria) in contradistinction to the tests on toxins. From the urticarial rashes produced by it he was led to believe that this serum excited a rapid interchange in the lymph circulation—that is, that it acted as a lymphagogue.

Three months ago he began trial of this remedy in phthisis, and the results encouraged him to extend his investigations to other diseases. These investigations cover nearly forty cases and many diseases, some of which are but recently placed under treatment. The writer, therefore, reports a short history of its results in but a few cases, prefacing these with a brief indication of its physiological action.

In a non-diphtheritic patient it gives rise to reactions largely dependent on dosage, diathesis, ailment, and local lesion. Under dosage it is convenient to divide the treatment into four periods, all or some of which may be absent:

(a) A period of initial fever, four to twenty-four hours after the first and second injection. This stage is very likely to be accompanied by reaction in the local lesions. In the normal individual this stage is absent or slight.

(b) A period of pseudo-vaccination, twenty-four to seventy-two hours after the third dose (second, fourth). This condition bears a strong clinical resemblance to symptoms seen in ordinary vaccination. There are large patches of erythema at the points of injection, most marked in the last; a chill (often slight) in some few cases, marked headache, urticarial rash, and sometimes considerable prostration. This stage lasts about twenty-four hours, and the patient has comparative immunity to further injections. It is after this stage is reached that one can expect beneficial therapeutic results in chronic disease.

(c) A period of sequelæ, eight to fourteen days after the second or third injection, in which secondary urticarial rash, arthritic pains, rarely an attack of subacute rheumatism or pains simulating neuritis, and sometimes a sore throat may occur. This stage has been recognized in the treatment of diphtheria and wrongfully attributed to septic infection. It seems to the writer to be due to an accentuated rheumatic diathesis.

(d) Period of comparative immunity from stages *a* and *b*. This period usually commences after pseudo-vaccination. He has seen one case of rheumatic diathesis in which he thought a mild attack of subacute rheumatism was provoked by the serum. Gouty and rheumatic patients are apparently more prone to urticarial rashes. The kind of serum is not solely responsible for these rashes. Many of his patients never had a rash—even those who received the greatest number of injections. The tuberculous patient has usually inflammatory action in the lesions.

The action in disease will depend on the stage, for when the system is aroused by this serum it seemingly exercises an intelligent choice of action. The following action of the serum was noticed from clinical observation: It increases saliva secretion; in a few days the dry, brown tongues of typhoid are replaced by clean, moist ones. With this change taste and appetite are restored toward normal. Constipation becomes lessened and in some cases disappears, and the stools become biliary and yellow under it. More milk is taken without curd appearing in the stools. The amount of urine is increased, and in

cases of scanty urine this has been a surprising feature. The heart action is made slower and the arterial tension increased; this may explain in part the increased urine. We have increased leucocytosis and a very great increase of the clotting power. It apparently acts powerfully on the pelvic lymph system. It will melt pelvic inflammation in two weeks as no other remedy can do. It has some action on the diseased endometrium. It apparently removed a severe and persistent attack of pruritus in one patient. It gives apparently excellent results in unhealthy granulation and sluggish ulcers. It has a decidedly favorable action on insomnia; restless nights are turned into refreshing sleep. This is due either to excretory adequacy or an excited internal secretion which induces sleep. It clears the atmosphere in depression from autotoxemia.

Before he narrates histories the writer mentions the diseased conditions in which the remedy is tried or being tried: Eight cases of pulmonary tuberculous lesion (renal, testicular, arthritis, glandular, meningeal, and laryngeal), sciatica, supposed mediastinal growth, a retroperitoneal mass of doubtful origin in a patient over fifty, multiple sarcoma or Hodgkin's disease, secondary pulmonary cancer, typhoid fever, enlarged spleen, pelvic peritonitis, some of the cases with salpingitis, endometritis, appendicitis, cystitis, multiple sclerosis, leucoderma, gonorrheal rheumatism, nephritis, erysipelas, and sepsis.

Dr. McPhedran (Toronto) placed a case of lupus under the serum. Some of these cases were seen in the practises of Drs. F. R. Eccles, J. B. Campbell, C. F. Nue, Teasdale, W. S. McDonald, and R. M. Bucke (London, Ontario).

CASE I.—W. J. R., aged twenty-five, had hemoptysis to syncope, October, 1894, and a recurrence every month or two during the following year. From November, 1895, they became more frequent. At this time speaking became more painful and his voice hoarse. In November, 1896, when he came under the writer's care, there were present the physical signs of extensive tuberculous involvement of left lung and pleura; in fact, the whole left chest was flattened and immovable. His weight was 142 pounds, and his chest expansion barely reached two inches. Tubercle bacilli found plentiful in sputum. He was able to take large daily doses of creosote (60 to 200 grains in enteric pill form) for months. He would improve for weeks, but a fresh hemorrhage would more than undo all the

gain. By March 1 his voice was reduced to a whisper. During April and May fever, restless nights and night sweats emaciated him to 122 pounds, and left him during the last of May bedridden. In spite of rest, opium, lead and ergot the hemorrhages became of daily occurrence in the last two weeks of May, blanching the patient.

This, then, was a picture of the author's first serum patient, and on June 1 he received his first dose of 250 units. Three days after a second dose of 250 units was given, and from this day 500 units were given thrice weekly till July 10. The first and second treatments decidedly increased the cough and expectoration. The hemorrhages ceased on June 4, and from that day to the present no tinge of blood has been seen in the sputum. By July 1 his voice was better than it had been for a year, and his strength very much recovered. During the first ten days of treatment he lost four pounds in weight; from this time to August his weight remained stationary. Since August 1 he gained a few pounds. Directly after the second dose the night sweats disappeared, and he began having refreshing sleep. On July 26 the writer ventured a second 1000 units, with a similar pleuritic attack resulting. He then gave him daily doses of 500 units till August 7, from which time till August 17 he gave him 1000 units every second day. From that date forward his dose was reduced to 1000 units every four or five days. Altogether he took over 25,000 units of diphtheria antitoxin. The physical signs apparently favorable from time to time reminded one of those of resolving pneumonia; and the ease with which sputum was expectorated was suggestive of the same thing. The clearing began at the base and traveled upwards. The crackling pleuritic sounds heard in the left chest on forced respiration before treatment have almost disappeared. His appetite and spirits are better than for eighteen months. Chest expansion three inches. The once immovable left chest has considerable expansive power now.

In the light of results in other cases, the writer thinks less frequent dosage would have been better for him, and while the serum by increasing the coagulability of the blood arrested the hemorrhage, yet in another patient with considerable tension 1000 units seemingly produced a hemorrhage by congestion of the local pulmonary lesion.

CASE II.—W. S., aged thirty-six, had tuberculous arthritis in left knee in 1875 and

1876. Five years ago the glands of his right neck became troublesome. These were removed in 1893. Three times in 1894 tuberculous glands were removed—twice by Dr. J. H. Cameron (Toronto) and once by Mr. Clutton (St. Thomas's Hospital). In February, 1897, Dr. Cameron removed some more glands, but on account of the brawny indurated skin being likewise tuberculous and other deeper glands beyond reach being infected, no radical removal was attempted. From the first two injections no result followed. The third of 1000 units was given August 7. On August 10, three days after the author saw the patient, his temperature reached 102° F. He had been afebrile before injections. The left knee had swollen and contained effusion, and some of the old scars there were painful and inflamed. The unre-moved glands of the neck were swollen and painful. The surgical incisions were red, and one of them in the next few days threatened to suppurate. The subsequent dosage did not have such a violent action.

Examined August 20: There was a softening and thinning of the indurated skin over neck. A favorable change took place in the tuberculous glands. There was diminished periadenitis, and they were less hard.

CASE III.—E. H., aged seventeen (Dr. A. McPhedran's patient). Lupus began at point of vaccination eleven years ago. She received four doses. Dr. McPhedran wishes the writer to say that when seen Friday, August 27, about ten days after the first dose, there were apparently beneficial results. He saw the patient himself on this date, and from her statement McCallum learned that this was the first time in eleven years the lupus was free from discharge.

A patient over fifty years of age had a retroperitoneal mass of two years' growth. It was greatly improved, less tender, more movable, and diminished in size. The accompanying insomnia was almost cured; he had five to seven hours' sleep in the night. In pulmonary cancer it apparently diminished the periadenitis and adenitis (superclavicular). It had a similar effect in Hodgkin's disease. The writer has already mentioned its action in pelvic disease. He does not mean to say it will remove a collection of pus, and yet in a case of gonorrheal salpingitis examined under chloroform by Drs. Meek and Eccles, something very much akin to that apparently took place.

To summarize, he suggests that as the beneficial effect of Behring's serum was not well

marked till several days elapsed and several injections had been given, it doubtless acts as a powerful lymphagogue or tissue arouser, such aroused condition being defensive to a degree against all invasion. The author cannot say whether all these effects, or some of them, cannot be obtained by ordinary horse serum. Dr. C. F. Nue has consented to undertake the task of seeing if several doses four or five days apart will render rabbits or guinea-pigs more resistant to various toxins than untreated animals.

Professor Richet, of Paris, in 1889 used horse serum to treat tuberculous patients. Dr. Coley, of New York, has shown that human subjects suffering from cancer are greatly benefited by injections of the toxins of streptococcus—apparently developing a kind of immunity to these toxins which is defensive against malignancy.

Treille (Foster, *Pract. Therapeutics*, vol. ii, p. 174) declares Behring's serum curative in malaria. Fournier (*ibid.*, vol. ii, p. 178) urges its use in grave scarlet fever angina. Dr. Williams, of Cardiff (*ibid.*, vol. ii, p. 7), mentions the beneficial effects of antistreptococcal serum in the delirium and insomnia of sepsis. Roux (*Annales de l'Inst. Past.*, 1894, p. 727) has shown that Behring's serum mixed with abrin retards the fatal effects of this poison.

Antitetanic serum has been shown by Calmette and Professor Fraser to be antidotal to snake venom. It has been long recognized that recovery from one infection often lessens the danger of another. Vedova (*Arch. Ital. di Path.*, 1897) claims that Behring's serum is specific for chronic fetid atrophic rhinitis due to the false diphtheria bacillus.

Howard Lilienthal (*Medical News*, July 17, 1897) reports one case of "hospital gangrene" in which staphylococci and streptococci were found, and one case of sepsis (with distended abdomen, rapid pulse, and a temperature of 106° F. six days after confinement) in which Behring's serum apparently led to recovery.

In conclusion, the writer points out that his results in any of these cases do not permit him to give his final word; indeed, it may be other serums would be found more potent, yet the result urges him to hope that some animals rendered immune to some other toxin or combination of toxins will give a serum with which curative results in tuberculosis and cancer may be more confidently expected.

*ON THE NON-SURGICAL TREATMENT OF BOILS, CARBUNCLES, AND FELONS.*

In the *British Medical Journal* of October 2, 1897, L. DUNCAN BULKLEY, of New York, publishes a paper on this subject, and first emphasizes the important fact that patients with boils, carbuncles and felons are never in perfect health, although it is sometimes difficult to discover exactly on what particular departure from health the condition depends; patient investigation, however, will generally afford the line upon which successful treatment will rest. Iron is most commonly needed, but quite as often there will be digestive and assimilative difficulties also to be overcome. Sometimes the cause lies only in overwork or worry; often in dissipation, though of a relatively harmless kind, involving late hours and irregular eating. The author cannot help dwelling as strongly as possible on this constitutional aspect of the question, for in this he finds himself at variance with much that is taught even in the best modern textbooks. In them this aspect appears to be regarded apparently as of relatively minor importance compared to the local treatment, whereas he regards it as of the first importance as compared to the relatively simple local treatment about to be described, which he has found thoroughly satisfactory.

The combination of iron which he has most commonly used in these affections is one which is known to us as Startin's mixture, somewhat according to the following formula:

- ℞ Ferri sulphatis, 1 drachm;  
Magnesiæ sulphatis, 6 drachms;  
Acidi sulphurici diluti, 4 drachms;  
Syrupi zingiberis, 4 drachms;  
Aqua, ad 3 ounces.

M. Sig.: One teaspoonful in water through a tube after meals.

Unless there is some counter-indication he generally begins treatment also with a good mercurial purge:

- ℞ Massæ hydrargyri,  
Extracti colocynth. co., āā 10 grains;  
Pulv. ipecac., 2 grains.

M. Div. in pil. No. iv. Take two at night and two on the second night after.

These four pills are generally repeated at the end of a week, and perhaps in other successive weeks.

Sulphide of calcium, if a perfectly fresh and good article and properly used, has in the author's experience a very decided and controlling effect over the process of suppuration. He always gives it in gelatin-coated pills, which he tests himself, for occasionally the drug will be found quite ineffect-

ive from having changed to the sulphate of lime or gypsum. To be efficient it should be given freely, one-fourth grain every two hours—say eight or ten doses in the day; this in connection with the iron tonic.

With these measures and a most careful attention to the diet and mode of life, the tendency to the suppurative process may generally be quickly overcome, as he has observed almost daily for many years.

The local treatment of the diseases under consideration which he has found very satisfactory differs materially from that commonly laid down, but can be briefly described. We will consider each affection separately:

1. *Furunculi*.—The objects aimed at by the treatment are: first, soothing and protecting an inflamed area; second, exclusion of air; and third, a slight antiseptic action. For this purpose a moderately thick layer of absorbent cotton is taken, several times the size of the inflamed surface: for a medium-sized boil a piece one by two inches, with the fibers running the long way. Upon the center of the cotton a considerable mass of the following ointment is spread by means of a spatula, and this is then laid over the boil, and held in place by strips of adhesive plaster across the ends, but not passing over the boil. The ointment referred to is generally composed about as follows:

- ℞ Acidi carbolici, 5 to 10 grains;  
Ext. ergotæ fld., 1 to 2 drachms;  
Pulv. amyli, 2 drachms;  
Zinci oxidi, 2 drachms;  
Unguent. aquæ rosæ, 1 ounce.

M. Ft. unguent.

The relief given by this dressing is often very marked; the ointment soothes and protects the irritated surface, while the layers of cotton take up any outside friction. If comfortable, and unless disturbed, this dressing remains untouched twelve or more hours, when it is removed and a freshly spread piece immediately reapplied. If there has been any discharge the surface may be very gently cleansed with absorbent cotton, but he does not allow any squeezing. In many instances with proper internal and general treatment the boil aborts, and subsides without discharging; when this does not happen, it ruptures spontaneously in a relatively short time, and he practically never finds it necessary to incise it. This treatment he uses in all stages of boils, keeping the ointment on until the boil is quite healed. If other boils form he directs it to be applied early, and by this means they are frequently aborted. He

wishes he could express in a measure some of the delight expressed by patients when thus dressed in the comfort and relief obtained, as compared with the sensations and results from other treatment which they have previously had. We should, he thinks, seek for the *jucunde* in our treatment as well as the *cito* and *tuto*, and from no small experience he can say that this treatment acts quite as quickly and surely as it does pleasantly.

2. *Carbuncles*.—As a carbuncle is in reality but a large boil, or a conglomeration of boils (with, of course, certain anatomical differences), the local treatment with the author has been much the same as that just described. Both early and late in the disease he has put on an ointment like the above, thickly spread on cotton, and fastened at the ends with strips of adhesive plaster. Not only on the back of the neck, but also on the face and elsewhere, this dressing proves most comfortable and serviceable, and he has not had occasion to incise a carbuncle since November, 1882—nearly fifteen years ago. The patient died from this and other complications, but there has not been a single case with such result in his practise since. He has applied this treatment to some large and formidable carbuncles, and has always thus far found that the pus would find exit rapidly enough, and the healing progress satisfactorily with this dressing. Occasionally it is necessary to aid in its expulsion by very slight squeezing or by removal of sloughs with the forceps. On some occasions febrile and other symptoms have at times seemed to warrant more active interference with the knife, but, although urged to it in consultation, he has adhered to this plan of treatment, without incision, and has obtained results which warranted its continued employment; and from previous experiences with cutting, and from cases thus treated by others, he believes that the method suggested has the preference, both as to time occupied and final results, whereas on the point of pain and general comfort of the treatment it is far superior. He is quite prepared to admit, however, that possibly from neglect or other cause a very large suppurating carbunculous area might be formed which would demand very active surgical procedure, such as curetting, or even excision, with antiseptic dressing, but under the treatment outlined this has never occurred.

3. *Felons*.—It will no doubt excite surprise and criticism when he urges somewhat the same line of treatment for the various de-

grees of inflammation about the ends of the fingers which are known as paronychia, whitlow, and felon; but, having treated a very considerable number of cases in this manner during the last fifteen or twenty years, he is prepared to advocate it strongly. The cases referred to include not only those of superficial character, about the nail, but also those very deep seated, on the pulp of the finger, even when there had already been sleepless nights from the deep-seated throbbing. The ointment used here has always been the diachylon, or litharge ointment, prepared according to the formula of Hebra. This particular form of ointment he considers to be important, for he has not found such good results from that made by melting the diachylon plaster with oil or vaselin, as more recently proposed. The diachylon ointment of Hebra is prepared as follows:

R Olei olivarium optimi, 15 drachms;  
Plumbi oxidi, 3 to 6 drachms;  
Olei lavandulae, 2 drachms.

M. Add the oil to two pounds of water, with constant stirring; the litharge is to be slowly sifted in while it is well stirred, fresh water being added as required. The ointment is to be stirred until cold, and the lavender added.

In winter a slightly larger quantity of oil is required to make a soft ointment. When properly made (and this is difficult to secure), this ointment is of a soft, buttery consistency, and quite sticky. The affected finger is to be plunged into the jar and a considerable quantity taken up, completely enveloping the first joint to a thickness of one-fourth of an inch. Over this are placed layers of absorbent cotton, and the whole loosely bound; sometimes it is more agreeable to spread the ointment on the cotton. It is generally desirable to renew the dressing about twice daily, but this is done with as little disturbance to the finger as possible, the old ointment being hardly disturbed, unless there is pus discharged.

The author cannot fully explain the benefit obtained by this dressing; but time and again he has seen the greatest relief, even after sleepless nights had been passed, and for many years he has prescribed this treatment with the greatest satisfaction and confidence. When applied early and in milder cases resolution takes place and no pus appears. But in those cases which are seen later or which are more severe pus forms and readily reaches the surface, and is either discharged spontaneously or by means of a painless prick through the dead skin. He has never had occasion to make the well known deep inci-

sion, even in certain cases where it seemed at first as if this would be required. He has repeatedly been surprised at the ease with which the pus has reached the surface. As remarked before, when it was necessary to aid its exit, this was done with a very superficial prick, entirely painless, and he has never seen any scar resulting.

It is quite possible that the most severe cases have not come under the author's observation, and he quite agrees that when pus has formed deep in the tissues and is burrowing under the tight fibrous bands which cross the tendons, a free surgical opening may be called for. But if taken reasonably early and the treatment intelligently carried out, he believes that in a very large proportion of cases the course will be such as he has before described.

#### CELANDINE IN CANCER OF THE FACE.

Dr. KRAINSKI, writing in the *Russian Ophthalmic Review*, records four cases of malignant disease of the eyelids and face in which he employed the celandine treatment. In two of the cases the neoplasms completely disappeared. In the other two there was distinct improvement, but the cases could not be followed up, and so the ultimate result cannot be stated. The time required for the destruction of the tumor was not more than a fortnight. Several injections were made in the sound tissue bordering upon the neoplasm. They were composed of equal parts of extract of chelidonium, sterilized water, and glycerin, four to eight minims of the mixture being introduced at a time. In addition to these a fifty-per-cent. solution of the extract in glycerin was applied externally twice a day and a dressing put on. The celandine did not affect the healthy tissues and was well tolerated by the conjunctiva. There was some pain for a few hours, and in two cases pyrexia. There was, too, a good deal of swelling around the tumor, and in one case suppuration at the situation of the punctures. Dr. Krainski has also given celandine internally in cases of cancer of internal organs where operation was impossible. A further paper is promised on this subject.—*The Lancet*.

#### THE CHOICE OF A MERCURIAL TREATMENT.

FOURNIER gives rules for administering mercury in different cases of syphilis. Leaving aside fumigation, baths, mercurial plas-

ters, etc., as antiquated, there remain three possible methods: (1) Ingestion; (2) inunction; (3) hypodermic injections.

The advantages of ingestion are: (a) Simplicity; (b) it being usually well tolerated by the mouth and intestinal tract; (c) its proved activity. The disadvantages are: (a) It may upset the digestion; (b) it is only tolerated in moderate doses, otherwise diarrhea and stomatitis appear; (c) it is therefore only suitable where a moderately active and not very rapid method is indicated.

The advantages of inunction are: (a) It is intensely active; (b) it does not, unless exceptionally, upset the digestion; (c) it leaves one free to give any other medicine by the stomach. The disadvantages are: (a) The trouble and time required are such that few patients will carry it out properly; (b) the course cannot be kept secret; (c) its curative effects are very unequal, probably depending on the way it is performed; (d) it is more likely than any other method to produce stomatitis of a very severe character.

As regards hypodermic injections there are two methods—namely, frequent or daily injections and occasional injections. The advantages of the former are: (a) It is an active method, whose activity can be regulated from day to day; (b) it does not upset digestion; (c) the stomach is free from other medicines. Its disadvantages are: (a) The possibility of local complications and the severe pain; (b) the impossibility of carrying it out properly outside a hospital. Occasionally injections are remarkably active, and sometimes work extraordinary cures not seen in any other treatment—such as the disappearance in a few days of large tuberculous syphilides, tertiary glossitis, gummatous laryngitis, etc. Of the disadvantages, some, such as stomatitis, are common to other methods; some, such as the almost inevitable injection nodules, are not of such importance; and some, such as phlegmonous inflammation, can be avoided by antiseptics. The great and unavoidable disadvantage is the pain. The author found that even such a small dose as  $\frac{1}{10}$  of a grain of calomel is often extremely painful. Of 400 calomel injections, the pain was bearable in two-fifths, intense in three-fifths, and in one-fifth of the latter intolerable. Many have therefore given up the treatment altogether. This is wrong, as it is very valuable in exceptional cases where a rapid effect is important or which do not yield to other treatment. Such cases are iritis and other ocular affections, ulcerated tuberculous syphilides, spread-

ing gummatous ulcerations, phagedenic chancre, gummatous laryngitis, etc. Exfoliative glossitis also often yields to no other treatment.

From the above summary certain indications are evident:

1. As regards the patient himself: If robust, ingestion will probably be most suitable, but if dyspeptic or cachectic this must be avoided; if his dentition is bad the best treatment is the perchloride by the mouth, inunction and occasional injection of large doses being altogether contraindicated. Injections are not to be used unless really necessary in workmen and others who live by the use of their limbs.

2. As regards the kind of syphilis: It may be roughly said that ordinary cases should be treated by ingestion, more severe by inunction, and the worst by injections.

3. As regards the object of the treatment: If it is for any particular symptom the course most suited for it must be chosen; if it is to cure the disease the first consideration is that the course must be a long one. Hence, owing to the disadvantages of inunctions and injections, ingestion is by far the best for this purpose, the course being interrupted now and then, but lasting for years.—*British Medical Journal*, Aug. 14, 1897.

#### POISONING BY METHYL BLUE.

The *Canadian Practitioner* for July, 1897, contains a report of three cases of poisoning by this substance, by HARRINGTON.

Seeing the report of the successful treatment of gonorrhea in the *British Medical Journal* of January 16, 1897, by James Moore, of Belfast, the writer adopted his plan and was exceedingly pleased with it in the small number of cases in which he gave it a trial. His prescription was:

Methylene blue, 3 grains;  
Potassium citrate, 15 grains.

To be administered three times a day, followed later on by an astringent injection of alum, three grains to an ounce of water three times a day.

On May 23 R. J. came to Harrington with an acute attack of gonorrhea, and he prescribed:

Methyl blue, 3 grains;  
Potassium citrate, 15 grains.

First konseal, mitte xii. One three times a day.

This prescription was put up by the same dispenser, and the patient took the first konseal at 2 P.M., and at 5.30 P.M. he had rather a distressing attack of vomiting. He came

to Harrington the same night, explaining his condition, and the writer concluded it had resulted from an irritable condition of his stomach, and advised him to continue his medicine. Saw him again on the 28th, and he said he had faithfully tried but could not retain it, and that it had purged him very much. The writer then made an investigation and found that the chemist had gotten a fresh supply of aniline, and that the new stock he had purchased was Merck's methyl blue (pyoktanin) and not methylene blue at all. In the first prescription he had written out the ingredient in full, methylene blue, but in the latter and in Cases 2 and 3, which had similar symptoms, he had abbreviated and written methyl blue, not thinking that methylene blue was an entirely different preparation from methyl blue or pyoktanin.

Cases 2 and 3 were similar, the main symptoms being vomiting and diarrhea.

#### LARGE DOSES OF ETHER IN THE TREATMENT OF UREMIC DYSPNEA.

After all that has been said of the injurious action of ether on the kidneys, it is interesting to learn that M. LEMOINE and M. GALLOIS, in a communication made to the Société de Biologie, an abstract of which appeared in the *Journal des Praticiens* of July 3, 1897, recommend its use in large doses in the treatment of various forms of nephritis, especially as a powerful means of mitigating and even curing dyspnea due to uremia. The authors state that one of them has employed this treatment for nearly ten years, and has succeeded in arresting with it the gravest forms of uremic respiratory disturbances, provided there was no actual renal lesion. It may be presumed that by this the authors mean no advanced lesion, for they go on to say that uremia due to acute nephritis, to acute renal congestion, to renal congestion occurring in the course of sclerotic nephritis, or to the infectious forms of nephritis, stands the greatest chance of being cured by means of the ether treatment. They aver that it is only the uremia depending on slow disorganization of the kidney by arteriosclerosis that does not yield to this treatment, although the comatose and convulsive forms are not readily affected by it.

The treatment consists in giving, every half hour or every hour, according to the severity of the case, two or three teaspoonfuls of ether in a little sweetened water. It is better, the authors say, to give part of the

ether subcutaneously—for example, to give a subcutaneous injection of two or three cubic centimeters of ether every three hours instead of the doses then due by the mouth. They say that they have given to some patients more than three hundred cubic centimeters without producing the least untoward effect, not even drunkenness; but it does not appear from the abstract into how many doses this amount was divided or whether it was given hypodermically or by the mouth. M. Lemoine and M. Gallois state that the ether occasions an abundant diuresis, improves the pulse, and relieves the respiratory spasm. They regard its employment as worthy to be classed with that of blood-letting so far as the result is concerned.—*New York Medical Journal*, July 24, 1897.

#### THE DIAGNOSTIC VALUE OF TUBERCULIN.

In the *Boston Medical and Surgical Journal* of August 5, 1897, FRANKLIN M. WHITE in writing on this subject points out that objections have been raised to the use of tuberculin, even for diagnostic purposes on the ground that there may be danger of poisoning the patient, or of stirring up latent tubercle bacilli and offering them a better opportunity for growth. He can only say that the method of diagnosis in his hands has been productive of no ill results, as far as he knows, beyond a day's discomfort to the patient, and that the occasional dangers of continued tuberculin treatment of tuberculosis in general, including advanced cases, have not been met with in using a single dose of tuberculin for diagnosis in incipient cases. When we see the brilliant results obtained in the diagnosis of tuberculosis in cattle by this method—a correct diagnosis in over ninety-nine per cent. of the cases—it seems as if a further experience in the observation of the reactions and a better knowledge of the most desirable dose were all that were necessary to make this a diagnostic method of the greatest value for man. It was a great advance when Koch gave us the method for finding the bacillus of tuberculosis, but before the diagnosis can be made by the microscope, it can usually be made without it. When we find the bacilli, our diagnosis is certain; but failure to find them does not exclude the disease. The tubercle test is much more helpful in early diagnosis. An injection will show the presence of the bacilli long before the inflammatory process is apparent to sight

or touch; and, on the other hand, a negative result gives absolute surety of freedom from tuberculosis, which of itself is often of the greatest value.

The author summarizes his views as follows:

1. The tuberculin method is simple and easily applied. An absence of reaction after injection indicates almost invariably an absence of tuberculosis more than four times out of five.
2. The method is especially applicable to the diagnosis of incipient pulmonary tuberculosis and of glandular, peritoneal, pleural and bone tuberculosis, where the bacilli cannot readily be found.
3. The general febrile reaction is a more generally useful diagnostic phenomenon than the local reaction.
4. The use of small preliminary doses of tuberculin is to be avoided on the ground of producing a gradual tolerance and a loss of general reaction.
5. The size of the best dose for diagnostic work is a matter for further study. It is probably between five and ten milligrammes for adults.
6. Ruedi's statement, that females react to tuberculin less readily than males, has not been confirmed by White's results.

#### THE TREATMENT OF ASTHMA BY ANTI-DIPHTHERITIC SERUM.

Basing his theory upon the principle that the channels through which drugs are eliminated are those where they exert their therapeutic action, REVILLIOD (*Rev. Méd. de la Suisse Romande*, Nov. 20, 1897) argues that the increased secretion seen after an injection of serum in all the mucous membranes, the similarity of the acne produced by the iodides, and the urticarial and multiform erythemata which are observed in asthmatic patients and in subjects treated by serum therapy, show that the mode of elimination of these drugs and the poison which Nature is attempting to eliminate in asthma are the same.

This reasoning led Revilliod to conclude that the aid which the iodides give to the asthmatic patient is assistance in the elimination of the particular noxious substance which is eliminated through the respiratory tract. And it is because of a similar physiological effect that he uses the serum, and not on account of any supposed antitoxic property.

The author reports a series of interesting

cases in which he injected antidiphtheritic serum in ten cubic centimeter doses during an attack; the action was almost immediate, and the crises did not return for nearly a month, when the injection was again repeated. In the first case the patient had had asthma for six years. An amelioration followed the first injection and increased after each injection, so that after ten injections made during five months the patient was completely cured. In the second case an asthma of seven months' duration was permanently cured in ten days by three injections. In the third case, of eight years' duration, six injections in two months resulted in a cure. In four other cases, although ameliorations have taken place, permanent cures have not been effected as yet.

The author does not believe that definite conclusions can be drawn from such a limited number of cases, but the successes which he has obtained lead him to believe that this method of treatment is worthy of the consideration and further study of the profession.

#### *PUERPERAL ECLAMPSIA: ITS ETIOLOGY AND TREATMENT.*

This subject, of never-ceasing interest to the general practitioner and obstetrician, is dealt with so practically by Dr. POTTER in the *Buffalo Medical and Surgical Journal* for September, 1897, that we have abstracted a large part of the article for our readers. Dr. Potter insists that in order to arrive at an intelligent treatment there must be a clear understanding of the conditions we are called upon to treat. It must be understood that we are dealing with a subtle toxemia not yet understood as to origin or material, nor even as to its *modus operandi*, but still one that arises from ingesta, intestinal putrefaction, and fetal metabolism, one or all, and that the organs of elimination are either sluggish or suspended in action. Symptomatically we usually have to contend with severe headache, edema, albuminous and scanty urine, diminished urea excretion, and finally, cyanosis, convulsions and coma, or semi-coma. The first group of symptoms pertain to the preeclamptic state and the last to true eclampsia.

Again, the woman may be anemic or plethoric, young or middle aged, a primipara or multipara, and the symptoms grave or moderate in their manifestations. Finally, the eclamptic seizure may be antepartum, intrapartum, or postpartum. All these factors

serve to modify or control the plan of the treatment to be proposed in a given case.

The treatment of eclampsia, too, should be classified into (a) preventive, and (b) curative. The preventive treatment may be subdivided into medicinal and hygienic, and the curative into medicinal and obstetric.

The preventive treatment of eclampsia affords an interesting field in which the clinician may display his talents and ingenuity in the application of hygienic measures and drugs to avert an impending danger of the gravest import. Given a pregnant woman in the seventh or eighth month with the prodromes of eclampsia—that is to say, who manifests the phenomena incident to the preeclamptic state—and what shall be done?

Manifestly, the first duty will be to interrogate the kidney as to its sufficiency and integrity. A qualitative and quantitative analysis of the urine must hence be made at the outset. Albuminuria is not a reliable symptom of renal disease or insufficiency, nor is a scanty twenty-four hours' output an unfailing index of kidney failure; nor yet is a diminution of urea excretion an infallible indication of approaching eclampsia. Exceptionally, all of these conditions may co-exist and yet eclampsia not result. These are indications singly and collectively that there is existing toxemia, that there is defective elimination, and that something must be done to correct a faulty relationship between nutrition and excretion.

If the prodromes and the physical signs are recognized early, it may be expected with reason that hygiene and medicine will correct the errors that are so rapidly tending toward eclampsia. Air, food, and drink must be supplied in ample quantities and of good quality; so, too, must we insist upon exercise, active or passive, walking, driving, light calisthenics or massage, according to the taste or tolerance of the patient. These are all good agents to employ, but the object sought should be to limit the source of toxins that are being absorbed and to promote their elimination.

One of the surest ways in which to control the supply of toxins appears to be, from abundant testimony, to place the woman upon an exclusive milk diet. This will serve at once not only to diminish the supply of toxins, but to increase the fluids of the body, flush the kidneys, and favor the elimination of toxic material. Water, too, should be freely given in definite quantities and at regular intervals. Distilled water is one of the best

diuretics that can be administered to a woman in the eclamptic state. Two quarts a day is not too much, and it may be given still or charged, according to the taste or desire of the patient.

The bowels of the preeclamptic, too, demand supervision. Constipation must not only be prevented, but intestinal toxins must be unloaded, and the intestinal tract kept free. These are commonplace observations perhaps, but they are essentials that cannot be omitted in a consecutive clinical picture of the management of a woman with eclamptic prodromes. Drugs are not specified in kind, but each physician will invoke the aid of an intelligent pharmacology. It should be remembered, however, that forcing the kidneys without supplying copious fluids is to be reprehended. Potassium salts that have been so frequently employed, and as the writer believes to the detriment of eclamptic patients, should be avoided. They favor the production of intestinal toxins, and beside tend to diminish red blood-corpuscles—an element that must be conserved.

There are two other remedies of which the author speaks because they belong to the therapeutics of the condition we are discussing—that is, the preeclamptic state. These are blood-letting and glonoin. If there is a full artery at the wrist with a tendency to cyanosis in the preeclamptic, venesection may be resorted to with benefit. One good full bleeding is permissible, but it should be used with caution in repetition. Its employment during an eclamptic seizure is to be feared, but here it is admissible, and in selected cases it will often prove beneficial. If there is high arterial tension—vasomotor spasm—glonoin in full doses is a valuable remedy. It combats this condition without depleting the patient, and, moreover, helps to set the kidney to work.

Let us now dismiss the preeclamptic state and consider the treatment of true eclampsia: Suppose a physician is summoned as a consultant in a case where convulsions have already set in—what is to be done? Here let us recall the three forms of eclampsia: (a) antepartum, (b) intrapartum, (c) postpartum. The treatment will be, first, medicinal, and second, obstetric. The first indication of treatment in antepartum eclampsia is to control the convulsions. An attempt wisely enough may be made to do this through the administration of chloroform by inhalation as well as the administration of chloral by the rectum. An eclamptic

woman swallows with difficulty or not at all, as she rarely rouses to full consciousness between the fits; hence it is better to administer chloral by the rectum. The writer prefers chloroform tentatively in these cases. If the convulsions are not promptly controlled or diminished in frequency or severity by its vigorous and skilful administration, he institutes measures at once to empty the uterus of its contents; and this brings us face to face with the most interesting question in the obstetric management of puerperal eclampsia.

A considerable experience has convinced the writer that a prompt evacuation of the uterus constitutes the most important method of dealing with eclampsia. While the womb remains gravid we are hampered in our therapeutics. Two lives are at stake, and in our anxiety to preserve both we may save neither. By addressing ourselves assiduously to a speedy delivery of the fetus we contribute in the largest manner to the conservation of both lives. With the fetus once delivered there is a freer opportunity to deal with the woman in the most masterful or even heroic manner. Fortunately eclampsia rarely occurs until the fetus has reached the period of viability, hence its speedy delivery becomes its greatest safeguard; for every hour increases its liability to death from maternal toxemia, as well as diminishes its chances of survival after premature delivery.

How many times has the fetus been destroyed by prolonged chloroform anesthesia, full morphinism, or extreme chloralization? One or all of these means, to be sure, may be used with comparative safety to the mother if the fetus is out of the way. How often, too, has the fetus succumbed to prolonged intoxication from the mother's blood?

If the author is called to an eclamptic woman who is within a month of term he lays down as a cardinal principle for his own guidance that it is his duty to proceed with all diligence to effect delivery. Why should not this be done? Will any one tell us why it is not good obstetric practise to proceed to aid Nature in the accomplishment of her own desires? Eclampsia is an expression of the economy that it has carried an offending fetus as long as it can be tolerated. The toxemia incident to its presence can no longer be endured without calamitous results, and eclampsia is but an expression of that fact—a danger signal. If we should appeal to statistics they would tell us that the mortality in antepartum eclampsia is seven

times greater than in postpartum eclampsia. Surely this speaks in no uncertain fashion commendatory of speedy delivery. But we are told that convulsions do not always cease after delivery. True, but is that a valid argument against the induction of labor? Postpartum hemorrhage does not always cease after the delivery of the placenta and secundines, but who will affirm that it is not proper in such a case to begin the treatment by clearing out the uterus? If convulsions continue after delivery we are now in a better position to push medicinal treatment, if need be, to its extreme limit than before. Purgatives, morphine, chloral, chloroform, diuretics and diaphoretics may all be employed with greater expectations and less danger than before delivery.

The writer has induced labor in a number of instances near the end of the eighth month, and always with most satisfactory result. In several of these cases, girls and boys now in the heyday of youth are living to gladden the hearts of mothers also rescued from a desperate strait. In no one instance has he ever regretted the induction of labor, while on the other hand he recalls a few times in which he has blamed himself for not invoking its aid. Occasionally, too, he has induced labor where there has been exaggerated preeclamptic conditions without convulsions—edema, albuminuria, semi-coma, and impending danger. These also have afforded gratifying results in living children and cured mothers.

Having determined to evacuate the uterus, how shall it be done? There are several methods recommended, but now one and then another seems applicable to a given case. For the most part, in antepartum eclampsia, dilatation, first practised with steel dilators if need be, then with manual stretching of the os and cervix, will accomplish the work to the best advantage. Exceptionally, however, extreme measures may become necessary, but only rarely can the deep incisions of Dührssen be required. So, too, should Cæsarian section be reserved for extreme complications like deformed pelvis, or to be done in the interest of the fetus when the mother's condition seems to be hopeless. In antepartum eclampsia, after obtaining dilatation, it is a good plan to terminate labor at once with the forceps under profound anesthesia.

In postpartum eclampsia the treatment must of necessity be medicinal, just as it must also be in the antepartum variety when convulsions continue after delivery. The

author has purposely avoided including *veratrum viride* in the group of medicinal agents which he would employ, because he deems it dangerous, uncertain, and deceptive in its action. It is but a symptomatic remedy at best, and it has always seemed that its employment was analogous to that of antipyretics in typhoid fever or pneumonia. These dangerous drugs seek to reduce the temperature at the expense of cardiac force without in any way exercising any influence over the real cause of the disease. So, too, with *veratrum* in eclampsia; it reduces arterial tension and cardiac pressure without exercising special influence over the progress of the malady. Moreover, it may easily be given to a dangerous degree even by careful hands. The author says he fears that many cases of eclampsia have succumbed to the indiscreet employment of *veratrum*, chloroform, chloral, and other powerful cardiac depressants; or, in other words, that these agents, though producing physiological action and apparently controlling the convulsions, yet do so at the expense of the tone and force of the heart muscle.

Blood-letting for similar reasons should be discreetly employed and limited to a few cases of the antepartum variety with plethoric habits and manifesting cyanosis. In the medicinal treatment principles are only discussed and not details. These latter will easily be supplied by experienced and well-trained physicians.

There remains one variety of eclampsia to be mentioned—namely, that of pregnancy as distinguished from eclampsia appearing just before, during, or after delivery. This form, though representing, statistically speaking, the most dangerous variety, nevertheless is one in which there is more time for deliberate action. It is here, too, that medicinal treatment offers better promise, hence the question of evacuating the uterus may be deferred until the other manifests failure and inadequacy.

Premature delivery may be induced in these cases by passing an aseptic bougie well up the fundus uteri externally to the membranes. Its extremity should be coiled within the vagina and retained by antiseptic packing. In a few hours labor will set in and can then be terminated rapidly if the occasion should so demand. Eclampsia occurs proportionately with greater frequency as the woman advances toward term, and *accouchement forcé* is more easily put into practise in the antepartum variety.

Finally, to promote the elimination of toxic material the value of diuresis, catharsis and diaphoresis should not be forgotten; neither should the means of the hot-air bath and the hot pack be overlooked.

*THYROID GLAND EXTRACT AS A GALACTAGOGUE, WITH A NOTE ON THE CLINICAL EXAMINATION OF MILK.*

In the *Intercolonial Medical Journal of Australia* STAWELL concludes a paper with the above title by the statement that while he is fully alive to the danger of making generalizations about treatment from insufficient data, and especially when the conclusions are based upon only a few clinical observations, it nevertheless seems that there is sufficient evidence to enable him to say that he has found the extract of thyroid gland to be an efficient galactagogue in certain cases, and that he has found the milk secreted under this influence to be of good nutritive quality. He thinks it improbable that, in the cases he quotes, any of the ordinary circumstances that cause a variation in the flow of milk existed markedly enough to have influenced in any way the nature and amount of the milk secreted, for he purposely refrained, in each case, from making any alteration in the general life and habits or diet of the nursing mother.

*THE SURGICAL TREATMENT OF RETRO-CÆCAL ABSCESS IN APPENDICITIS.*

Dr. DURET, of Lille, read a paper upon "The Surgical Treatment of Retro-Cæcal Abscess in Appendicitis" at the French Congress of Surgery, held at Paris on October 18-23, 1897. He stated that these abscesses are necessarily of common occurrence, as the appendix is situated behind the cæcum in more than twenty per cent. of the bodies which have been examined to ascertain its exact position. Besides, a certain number of these abscesses are caused by infection from a distance, the infective material being brought by the veins and lymphatics to an appendix which may or may not be normally situated. A retro-cæcal abscess is characterized by a swelling in the right flank, which is well marked, even when the abscess is small. Usually such an abscess seems to be situated just behind the abdominal wall and in contact with it, so that it appears as if the abscess could easily be opened and the pus

evacuated without any danger, as the communication with the peritoneal cavity is cut off by adhesions. An incision, however, always shows how serious an error has been made in diagnosis. The peritoneal cavity is always opened, and a certain quantity of serous or turbid fluid escapes. There are no adhesions, the distended cæcum is at once seen, and unless the greatest care is taken pus deluges the peritoneum.

Dr. Duret recommends the following treatment to avoid disaster in these cases: First, to isolate the cæcum completely from the rest of the peritoneal cavity after the abdomen has been opened by fixing the parietal layer of the peritoneum to the cæcum with a continuous suture, and closing the two ends of the wound with two small pieces of iodoform gauze; second, opening the abscess by Hilton's method or with the point of the finger at the outer border of the cæcum, then emptying, scraping, and swabbing it; third, draining and Mikuliczing it, and sometimes making a counter opening in the lumbar region; fourth, suturing the abdominal wall in three places to prevent subsequent hernia.

Dr. Duret gives details of several instructive cases treated in this manner where recovery took place without any accident.—*Treatment*, Nov. 25, 1897.

---

*THE DIAGNOSTIC AND THERAPEUTIC VALUE OF "LUMBAR PUNCTURE."*

MONTI (*Medical Press and Circular*, Dec. 1, 1897) reaches the following conclusions as a result of his study of this subject:

1. Tapping, as a diagnostic or therapeutic adjunct, is quite worthless according to his own experiments; but it must be borne in mind that other investigators have discovered in the cerebro-spinal fluid proof positive of the tuberculous bacillus, as well as cultivation in other animals, to justify the assertion that it is constantly present. His own opinion is that a negative result does not destroy a positive clinical diagnosis.

2. In acute cases of meningitis cerebro-spinalis the cerebral fluid does not contain morbid products which, if applied to animals, as Heubner has shown, may serve to verify clinical observation.

3. When the acute stage has been passed and hydrocephalus is present, no diagnostic assistance can be obtained from the examination of the fluid.

4. As a therapeutic agent it is equally inefficacious in meningitis cerebro-spinalis and

meningitis tuberculosa. The author qualifies this by saying that individual cases do improve when operated on early, often repeated, and large quantities abstracted. He recollects one in private practise of two months' standing that improved after each tapping, but ultimately died after three days' illness.

5. The writer states that his experiments are not sufficiently large in meningitis, chronic hydrocephalus, or chronic hydrocephalus in connection with tumors, to justify a critical record of their worth.

6. Further experiments are necessary to determine the quantity of fluid to be abstracted, the interval of time that should elapse between the operations, and how far the therapeutical value, if any, can be demonstrated.

#### *A NEW METHOD FOR THE RADICAL CURE OF INGUINAL HERNIA.*

Of the invention of new methods for the radical cure of inguinal hernia there seems to be no end, and the constant occupation of surgical ingenuity upon this subject may be taken as an indication that no perfectly satisfactory method has so far been devised.

The latest contribution in the way of a new method of operating comes from Dr. George Ryerson Fowler, professor of surgery in the New York Polyclinic, who, in an instructive and well illustrated article published in the *Annals of Surgery* for November, 1897, argues that the methods of operation now in vogue, namely, that which bears the name of Bassini, with its modifications devised by Halsted and others, leave a weak spot in the abdominal wall at the internal ring, owing to the funnel-shaped protrusion of the ligatured sac, and the emergence of the cord at this point, which invite the recurrence of the hernia.

McEwen's method of avoiding this defect, by fixing the folded sac under the internal ring, Fowler criticizes as difficult to exercise satisfactorily. Kocher's method of drawing the displaced sac outward through an opening in the aponeurosis of the external oblique toward the anterior spine of the ilium, and attempting to close the canal without incising its anterior wall, is only applicable in cases without pathological alterations of the sac, and is mechanically a faulty method. Attempts to modify Halsted's operation, by directing the cord upward and outward for a short distance on its emergence from the abdominal wall and fixing it by sutures, have proved unsuccessful, as the weight of the

testicle soon proved sufficient to drag the cord down into its normal direction.

As a result of recent experiences in which herniæ have recurred in adults after operations which followed the essential feature of the Bassini operation—namely, the displacement of the cord directly forward through the internal ring and muscular parietes—Fowler has devised a method the essential feature of which consists of an intraperitoneal or backward displacement of the spermatic cord, allowing the complete closure of the internal ring by sutures. The essential features of the operation are the following: (1) A curved incision of the skin, allowing a flap to be turned upward, and exposing the canal, the anterior wall of which is incised; (2) separation and isolation of the sac and cord; (3) cutting away the sac at the level of the abdominal wall; (4) isolation of the deep epigastric artery and vein, and their division between ligatures; (5) incision of the posterior wall of the canal, including the transversalis fascia and peritoneum, upon the finger inserted through the neck of the sac. The operation is then completed by placing the spermatic cord within the peritoneal cavity, and uniting the transversalis fascia and peritoneum by broad approximation sutures in front of it until the lower end of the gap in the posterior wall of the original inguinal canal is almost reached. The cord is then brought forward through the newly formed external ring.

The canal is now closed by sutures of kangaroo tendon, which include the conjoined tendon and the aponeurosis of the external oblique upon the inner margin, and Poupart's ligament upon the outer; the new point of emergence of the cord is strengthened by the displacement outward of the pubic attachment of the corresponding rectus muscle.

Fowler commends his method as the only one which allows obliteration of the internal ring and inguinal canal, and has employed it in six cases, which, however, are of too recent date to allow of any estimate of permanent results. Although this method has certain features to commend it, the simpler operations of Bassini and Halsted with their modifications have of recent years met with such pronounced success that there can be no doubt of their efficiency in a large proportion of cases; and in those which present no extraordinary difficulties, there would seem to be no reason for discarding them for a method which is complicated by the additional steps of tying the deep epigastric ar-

tery and making an extensive incision into the peritoneum.

The conditions presented to the operator by different cases of hernia vary so greatly that no one method can promise success in every case. Experience may prove that in certain cases of large and long-existing herniæ in adults, in which the whole posterior wall of the inguinal canal is stretched and protruded forward, and in which there is marked stretching and atrophy of the muscular and aponeurotic structures, Fowler's method will have distinct value. The operation is certainly ingenious, and is devised to meet certain well known faults of the older procedures as applied to this class of cases.

Up to the present time no perfectly satisfactory method of disposing of the cord in these cases without the extremely undesirable alternative of castration has been devised. If Dr. Fowler's method shall prove to have solved this problem, it will have very definite value.—*Boston Medical and Surgical Journal*, Nov. 18, 1897.

#### *INJURIES TO THE SKULL, INVOLVING THE BRAIN, ITS COVERINGS, AND CIRCULATION.*

In the *International Journal of Surgery* for November, 1897, EARLES presents an interesting paper, in which he calls attention to the fact that Horsley has clearly established that brain scars, scars in the dura and depressed fragments of bone frequently cause epilepsy, and that the removal of those causes usually results in benefit to, and often in cure of, the patient. With this well defined and demonstrated proposition before us, combined and taken in connection with other clinical facts equally well established, we have reasonably safe guides to follow in the treatment of all head injuries. In attempting to outline a general plan of treatment, we should place in the rank of first importance surgical cleanliness. Without this no one can hope to do satisfactory work upon the skull, its coverings, or its contents. We must not forget that infection is easily carried from the scalp to the brain or its coverings, through the channels already referred to, and that such an occurrence cannot be too profoundly regretted. When resulting through the carelessness or unsurgical habits of the medical attendant, it cannot be too emphatically condemned. The experience of all who work in this particular field goes to prove that we can enter the cavity of the skull, and there

deal with conditions demanding surgical attention, with the same confidence and assurance of securing desired results that we possess when we enter the abdominal cavity, providing we exercise the same care and practise the same cleanliness.

In all operations upon the skull, the entire head should be shaved and thoroughly disinfected before the skull wall is opened. All foreign matter should be thoroughly removed, even though the chisel and hammer be necessary for the accomplishment of this result. The latter is often necessary where dirt, hair, etc., become lodged in the line of fracture. The surgeon's hands, instruments, etc., should be thoroughly disinfected, and nothing of whatever kind or nature allowed to touch the wounds except that which is known to be surgically clean. The next care of the surgeon is to ascertain, if possible, the nature and extent of the injury. If there be a fracture with depression, this can only be done by exploration. Removal of a section of bone, either with the trephine or chisel, places the field of injury within visual observation, and clears up questions that must otherwise remain in doubt. In all cases sufficient bone should be removed to permit of a thorough inspection of the field of operation. With the injured parts before us and readily reached, we treat them as we treat injured structures in other parts of the body. All foreign matter and blood-clots are to be removed, the parts thoroughly cleansed, and hemorrhage controlled either by hot applications, pressure, or the ligature. If these methods fail to control the hemorrhage, an iodoform gauze tampon may be used. After thorough cleansing and control of hemorrhage, any ragged edges in the wound must be removed, securing, if possible, smooth, coapting surfaces. The wound in the brain should first be closed with catgut sutures. The wound in the dura mater is then carefully united with catgut, and the scalp wound closed in the usual way, with or without drainage.

When the operator has reason to believe that his work has been aseptic throughout there is no necessity of drainage. When, however, he has reason to fear subsequent septic trouble, it is safer practise to insert a gauze or rubber tube drain. A few strands of catgut often serve a good purpose by draining such wounds of their accompanying and unavoidable exudate. The patient must be put at physical and mental rest, and his condition closely watched for at least ten days. Any evidence of septic disturbances

about the wound demands prompt interference on the part of the attendant. The scalp must be opened up and the parts thoroughly irrigated and cleansed. If the trouble be deeper seated, the dura must be opened and drainage inserted. In short, having failed to secure an aseptic result, we must now rigidly enforce the antiseptic line of treatment until healing is complete.

It must not be forgotten that the granulation and scar tissue resulting in wounds that do not heal by first intention are prone to be followed by dreaded remote effects which are often immeasurably worse than death. Even a cicatrix of the scalp has been known to be followed by epileptic seizures, while scars in brain tissue or dura mater are classed by all as among the prime factors in the causation of this much dreaded and mysterious malady. We should, therefore, leave nothing undone that can in any way conduce to or further the prospects of healing by first intention, for while we may without it secure reasonably satisfactory immediate results, we cannot hope for satisfactory remote ones.

In the event of epilepsy or other serious manifestations following injury to the head, it is the plain duty of the surgeon to look for the cause, and if found, to remove it as soon as may be. Opening down upon the supposed seat of injury, either with trephine, chisel, or both, the depressed bone should be elevated or removed, and any scar tissue found, either in brain or dura, must be excised. This can be done with almost perfect safety if ordinary care and surgical cleanliness be observed. The happy effects of such operations are often manifest, and while we are still in doubt as to their *modus operandi*, the results, at least, are very gratifying. Even if we admit that the so-called cures of traumatic epilepsy through operation are entirely due to the moral effect, the results are no less valuable to the patient. Each case should be carefully studied in all its details, and should be treated in and according to the light which the researches, observations and clinical experiences of the past have furnished.

#### *SYPHILIS OF THE NOSE, THROAT, AND LARYNX.*

VAUGHAN (*Medical News*, Nov. 20, 1897) says that the diagnosis of a syphilitic ulcer in the pharynx is sometimes very difficult to make, but one cannot be far wrong in suspecting any ulcer occurring in the throat which has a floor covered by a dirty purulent

slough, and which is surrounded by angry looking, very much inflamed mucous membrane. It has been the author's good fortune to observe several cases of tuberculous ulceration of the pharynx, and of malignant disease of the tonsils, which simulated very closely ulcers of syphilitic origin, and in which the diagnosis was determined with great difficulty. If ulceration has already commenced in malignant disease of the tonsil before the patient presents himself for examination, the differential diagnosis will be difficult; but when one bears in mind the history of the case; the fact that tuberculosis and malignant disease of the pharynx are rather rare conditions; that tertiary syphilis in this locality is commonly observed; that the syphilitic condition responds readily to treatment, while malignant tonsillar disease is not materially benefited; and that tuberculous disease of the pharynx is positively made worse, and all the symptoms of tuberculosis increased by antisyphilitic treatment, the diagnosis is somewhat simplified. A very safe rule, and one recommended highly by Lennox Browne, is to put the patient upon treatment for syphilis, and have him weighed daily. If he gains in weight steadily for several weeks the trouble usually is of specific origin; if he gains in weight for several days and then begins to lose, the affection probably is malignant; while if all the symptoms are intensified, the probability is that the disease is of a tuberculous nature.

The author has never seen a primary sore situated in the larynx, but the erythema, mucous patch, ulcerative process, and gumata, followed later by breaking down of the gummy tumor and subsequent formation of cicatricial tissue and occurrence of stenosis of the larynx in various degrees, are, with the possible exception of the mucous patch, common pictures to the laryngologist.

A quite marked symptom in a great many cases of syphilis in its early stage is the appearance of laryngeal catarrh, and only in one particular does this differ from an ordinary catarrh, the last named variety being usually relieved by topical applications, while they are only of limited value in the specific type, one being compelled to resort to antisyphilitic treatment in order to relieve the condition. The erythema is not so marked and is not so characteristic as when present in the pharynx, but it is sufficiently noticeable, particularly when associated with alternate patches of red and white situated on vocal cords, to lead one to suspect its specific

origin. Pain is generally absent. The condition may last a long time if untreated, but shows no tendency to pass into one of the graver manifestations of syphilis. If the vocal cords are involved there may be much impairment of the voice; in fact, sometimes the voice is completely lost. Mucous patches are of exceedingly rare occurrence in the pharynx, but when present are generally situated upon the upper surface and free margin of the epiglottis, on the arytenoids, or on the false vocal cords, sometimes being found on the interarytenoid commissure. The mucous patch in this condition, as elsewhere in the body, is resistant to treatment, and is very likely to recur.

Probably the most common manifestation of the disease in its tertiary form in the larynx is ulceration. This is preceded by an infiltration of the mucous membrane with inflammatory products, and is usually diffuse in character. Gummata are commonly situated near the posterior commissure, upon the arytenoid cartilages and epiglottis. At first they are small and of the same color as the contiguous membrane, but gradually they enlarge, soften, a small yellow spot appears in the center of each gumma, and finally a destructive ulcerative process begins. This is usually rapid, and frequently large areas are completely destroyed. When it occurs on the epiglottis entire destruction of the valve may occur before the patient can be brought under the influence of medicine. When much tissue has been destroyed there will, of course, after healing begins, be a formation of cicatrices, with resulting stenosis, and sometimes distortion of the larynx. When this occurs, the voice is permanently much altered in character.

In regard to the treatment of syphilis, when occurring in the nose, throat, and larynx, the author knows that to await the development of secondary symptoms, and then begin constitutional treatment, is the better course to pursue; but it appears to him that more favorable results are obtained when the patient is put upon some one of the mercurial salts as soon as the diagnosis of syphilitic infection is absolutely decided upon. Local cleansing of the primary sore with some mild antiseptic, as boracic acid solution, or better still, with iodoform (a most efficient but disagreeable remedy on account of its penetrating odor), is all that will be necessary during the first stage. Caustics locally applied during this stage undoubtedly do harm. Upon the appearance of secondary symptoms, either

inunctions with mercurial ointment, or the internal administration of some salt of mercury, will cause subsidence of the symptoms. When a mucous patch occurs, it should be touched repeatedly with tincture of iodine or solid nitrate of silver. Catarrh of syphilitic origin requires the administration of ferruginous preparations, and the spraying of the nasopharynx with mild antiseptic and alkaline solutions. In the coryza occurring in infants, the nose should be sprayed *cautiously* with a weak solution (two and a half grains to the ounce) of cocaine, or better still, should be cleansed, particularly when the crusts are very adherent, with a ten-per-cent. solution of menthol in olive oil. Menthol is somewhat similar in its action to cocaine; its anesthetic action is very much less, but it is particularly effective in that it relieves the congestion of the turbinate bodies and allows respiration to take place through the nasal passages. Upon the appearance of tertiary manifestations the administration of iodide of potassium or sodium is indicated, beginning with doses of from five to ten grains three times a day, depending upon the tolerance of the patient, and increasing it several grains daily until the progress of the disease is checked. In some cases it is best to combine the iodide with mercurial inunctions. It must also be kept constantly in mind that the alimentary canal, the excretory apparatus and the skin must receive particular attention. Wholesome, nutritious food is absolutely essential to a sound condition of the alimentary tract. Mild salines and laxatives are occasionally required to stimulate excretion; and nothing is of more benefit in keeping the skin in a healthy condition than warm or hot bathing, which should be regulated by the attending physician. Smoking and the drinking of alcoholic beverages should be prohibited.

---

**REMOVAL OF AN ANGIOMA OF THE  
LIVER BY ELASTIC CONSTRUCTION  
EXTERNAL TO THE  
ABDOMINAL CAVITY.**

KEEN, in the *Pennsylvania Medical Journal* for October, 1897, details his experience in this class of cases. The conclusions that the author has reached are as follows:

1. Experiments upon animals and operations on man have shown that tumors of the liver and even large portions of the liver can be removed without undue disturbance of its function. Experimental evidence in animals and clinical evidence in man go to show that

the liver tissue is regenerated and the loss made good (Ponfick).

2. That the escape of bile into the peritoneal cavity is not usual after such an operation; that by searing the raw surface, by ligation, by walling off with gauze, and by securing the stump in the abdominal wall, it is prevented, and even if it occurs, fresh bile is not infective, and therefore does not produce peritonitis.

3. The two dangers of hepatic operations are sepsis and hemorrhage, especially the latter. The former can be prevented by modern antiseptic methods; the latter can be mastered by ligation, by the cautery, by the elastic ligature, or by pressure, or still better, by a combination of these means.

4. The removal of a tumor can be done by ligation, by blunt dissection, by the cautery, by the knife or scissors, or by a combination of these methods. If the base is very large or the tumor very vascular, an artificial pedicle can be made by the cautery and an elastic ligature applied.

5. In case a syphilitic tumor is suspected, no operation should be done until after a full trial of antisyphilitic treatment has been made and failed. The case of Athenstiel (*Archiv. Klin. Chir.*, 211, 902), in which an abdominal section revealed the syphilitic nature of the large tumor, is most instructive. The operation was at once terminated, the abdomen was closed, and the patient entirely recovered under suitable treatment.

6. In all cases of doubt, and after a fair trial of antisyphilitic treatment, provided time allows, an exploratory celiotomy should be done. If the case is unsuitable for operation, because it is syphilitic or by reason of its size, adhesions, multiplicity of tumors, or for any other similar reason, the abdomen is simply closed and very rarely will any mischief be done.

On the other hand, if, as will very frequently be the fact, the case proves to be operable, suitable surgical measures can be immediately instituted.

#### TREATMENT OF INFECTED WOUNDS BY FORMOL AND PARACHLOROPHENOL.

LE DENTU (*Revue de Chirurgie*, No. 11, 1897) states that since the sterilizing power of formol is twice as great as that of sublimate solution, a lotion of 1:200 is ten times as potent as a sublimate solution of 1:1000; moreover, formol has an extraordinary deodorizing faculty, gangrenous tissues instantly

losing their mephitic qualities when irrigated with a solution of 1:200. Hence formol is a disinfectant and sterilizing agent of the first rank. Parachlorophenol is five times as potent as carbolic acid, has less odor, is less irritating, is less toxic, though it is readily absorbed and may act violently on the kidneys.

#### ABDOMINAL CONTUSIONS.

DEMONS (*La Semaine Médicale*, October, 1897) describes three results of abdominal contusions: (1) Injury of the abdominal wall; (2) injury of one or more organs; (3) injury of intra-abdominal organs while the abdominal wall escapes. It is often difficult to determine the force or extent of the injury. Details, even the shape of the wounding agent, are important. Narrow bodies, the action of which is exerted on a small area, reach more deeply by overcoming resistance of the abdominal parietes more easily than larger bodies. Resistance varies with the age, state of obesity, state of relaxation or contraction of the muscles. The direction of the blow is of importance. If perpendicular to the deeper structures, it is most harmful; when parallel, it tends to glide off; when oblique, the force is modified. Fragility varies with the different viscera or with the anatomical or pathological conditions at the time of the accident. Hollow viscera are more vulnerable when distended. Laceration is favored by morbid changes in the viscera. Immediate symptoms of such an accident vary. Pain is usual, but may be slight or severe, local or general, spontaneous or determined by pressure. Deep seated localized pain points to a wounded viscus. Sharper pain usually points to contusion of the abdominal wall. Ecchymoses or superficial swelling is of no diagnostic value for deeper injuries. Vomiting or slight tympanites does not afford any reliable evidence of injury. Rigidity of the abdominal walls, though not constant, is an important indication of visceral lesion, and almost characteristic of a wounded viscus. Diagnosis is often easy, but may be very difficult. Fractures of the skull, spine or limbs may mask other symptoms. With a hollow viscus severe contusion or slight perforation may give the same symptoms. Exploratory laparotomy should not be resorted to in extremely mild or severe cases. Whenever advisable it should be performed as early as possible—within twenty-four hours of the accident.—*British Medical Journal*, Nov. 27, 1897.

*THE TREATMENT OF COXALGIA.*

MÉNARD (*Revue de Chirurgie*, No. 11, 1897) has treated 615 cases of coxalgia; 261 were of the dry form, and aside from osteotomy were not subject to any surgical intervention. During the first and second periods the patients were put in bed and subjected to continuous extension, supplemented by immobilization when the disease was rapidly advancing. During convalescence these patients were gotten up with crutches and a fixation apparatus. In cases complicated by abscesses camphorated naphthol injections were used; of 108 such cases ninety-four recovered and six developed fistulæ. Abscess was generally preceded by pain, which was not relieved by rest or extension, but promptly yielded to a plaster dressing running from the armpit to the foot. The injections which cured the abscesses also led to a comparatively rapid cure of the hip disease. Even if they are not successful they render subsequent resection safer. In 146 cases the coxalgia was complicated by fistulæ, which usually developed before the patient entered the hospital. In fifty-five of these cases the fistulæ closed spontaneously without intervention. This usually occurred in infants from three to seven years old. Twenty-seven cases of coxalgia were subjected to resection before having been admitted to the hospital; seven were cured; nineteen still exhibit a fistula. Injections are futile in the cure of these fistulæ, since they do not penetrate to a sufficient depth. Drainage is also useless. When there is persistent, abundant suppuration and new abscesses form, and especially when the general health is declining, resection is always indicated.

The reporter resected seventy-four times in cases of coxalgia complicated by fistulæ. As little of the femur was removed as practicable to expose the joint, and in but six cases was a subtrochanteric section made. The ilium was the common seat of serious and persistent lesions. In thirty-one cases there was perforation of this bone, with more or less extensive intrapelvic granulations. The bone was removed very freely in six cases. Twice an attempt was made to secure union by first intention and was successful. Usually the wounds were drained. Consecutive curettage after resection was practised in seventeen cases; thirty-four recovered without fistulæ; fourteen left the hospital with fistulæ; three died. Hip-joint amputation was performed in four cases, and nineteen cases were still under observation.

Of the 615 cases observed twenty-four died—nine without operation (three of meningitis, two of visceral tuberculosis, and four of cachexia), fifteen after operation (four of operative shock, three of meningitis, three of cachexia, and five of tuberculosis). In patients carefully treated from the beginning of the affection luxation and cold abscesses only developed in the most serious cases. Cold abscesses are nearly always cured by injection; fistulæ are exceptional. When fistula has once been established spontaneous cure is less likely to occur and the results of operation are less favorable.

*REDUCTION OF CONGENITAL LUXATION OF THE HIP.*

LORENZ (*Revue de Chirurgie*, No. 11, 1897) has attempted reduction in 160 such cases and has had but five failures. The conditions essential to reduction are that the head of the femur should be brought in close proximity to the acetabulum and that the thigh should be carried in abduction to an angle of 90°, thus mobilizing the head of the femur. This is accomplished by flexing the thigh until it makes a right angle to the plane of the body, thus bringing the head of the femur behind at the posterior margin of the acetabulum. Vigorous traction is then made upon the femur in the direction of its long axis when it is flexed, and at the same time the bone is abducted through 90° of a circle, when succussion will denote that the end of the bone has slipped into place. At the same moment the thigh becomes longer and the head of the bone can be found in the inguinal fold.

*THE FORCIBLE REDUCTION OF SPINAL CURVATURES.*

PARKIN (*The Clinical Journal*, Nov. 17, 1897) contributes an interesting addition to our knowledge on this subject. He states that during the last six years he has had at the Children's Hospital many cases of spinal disease under his care, and naturally the degree of severity has been varied. He has had in all eight patients on whom he performed laminectomy. His object in doing laminectomy was to relieve the paralysis present to a greater or less extent in each case; but besides this the writer has found that after the operation it was as a rule very easy to correct more or less completely the deformity present. The author's idea of a properly performed laminectomy comprises removal of

the spines and laminæ over the portion of diseased spine, so as to relieve the pressure, if any, on the cord; next, the location of the disease in the affected vertebra and careful removal of all caseous material that can be got at, no matter whether one, two, or more vertebræ are affected; finally, when the wound is sewn up, with the help of assistants, the patient is held in such a position that the previously existing deformity is obliterated more or less completely according to the duration of the deformity in each case.

In cases of cervical disease the author has had strong traction made on the head whilst a poroplastic splint or plaster jacket was adapted to the upper part of chest and head. If in lower parts of the spine, he has had traction also made, whilst fixing a plaster jacket; and at the same time he has had upward pressure applied to the affected region, the patient being in the supine position, so that the spine at the diseased part was unfolded and made to assume a curve much more nearly resembling the normal. Such manipulations in no way interfere with the future comfort of the patient, and they certainly have an advantage from an esthetic point of view in the results obtained.

In all probability the manipulation required is less severe when the spine and laminæ have been removed than when this has not been done, for in old cases of caries there is often a certain amount of adhesion between the laminæ, as can be seen in museum specimens. It is not necessary to employ very severe traction to obtain the desired result.

During the convalescent stage, if the deformity has not been completely reduced Parkin has at a later date put the patient up again in plaster-of-Paris jacket, in such manner that the deformity is still further reduced. He has done this by suspending the patient by a bandage about four inches wide passed under the most prominent part of the spine, this bandage being attached to a movable bar, which can be raised if necessary until the patient's head and heels only touch the ground; this, it will be readily seen, allows the weight of the body at each end to unfold the spine still further. Sayre's jacket is then applied, and when sufficiently dry the bandage is cut, and the patient put back to bed. This mode of application has been adopted several times without the patients being at all inconvenienced, and he looks upon it as a valuable means of diminishing spinal deformity.

Even in ordinary cases of caries this mode

of application of a plaster jacket has many advantages. In the ordinary or vertical form of application the idea is that the weight of the body tends to straighten the spine. Obviously no one needs or wishes for a straight spine—*i.e.*, a spine straightened throughout; but what is advantageous is to have rectification or straightening of the spine at the spot where there is a tendency to undue flexion or undue extension; this is readily obtained in the manner described. Besides, the vertical position is very fatiguing and difficult to maintain until the plaster is set, and it is no unusual thing for a patient to faint during applications; whereas by the method in question the patient is more or less horizontal, the position can be steadily maintained whilst the bandages are carefully applied and until the jacket is sufficiently set, and the patient can be at once placed in front of the fire to dry without risk of breaking the jacket. The removal, as complete as possible, of all tubercular matter cuts short the course of disease. None of the reporter's cases (some of them of the worst type of spinal caries) were after operation confined to bed for more than three months, with the exception of one in which a general spread of tubercular infection occurred, which is only too common in cases not so treated; whereas similar cases of caries not operated upon block up hospital beds for many months, and then frequently drift to the infirmary or the workhouse. It would be advantageous to have reliable statistics of cases of spinal caries, with a view of ascertaining what proportion of hospital patients really get cured. It is surprising how they drift about, getting "cured" at one hospital to apply to another; and when they get worse or die it is considered only a natural result. So far the writer has followed up his own cases, and it has surprised him to find so many dying after a variable period. The worst cases and the least promising in every way have been those on which he has done laminectomy, and these are the very cases that have stood best the lapse of time, since all those referred to were operated upon over three years ago, and one of them more than five years ago.

It has been argued against laminectomy that it interferes considerably with the spine as a basis of support, and that it results in restricted movement of the back. Would it not be more accurate to state that the disease for which the operation is undertaken (caries) is really the true cause for both? For the centra are first undermined, and then the

weight of the head or upper part of the body is constantly transmitted through a weakened spine in such a manner as to produce deformity and rigidity, the latter at first muscular, tending to counteract the deformity, which finally becomes more or less fixed, producing a pathological rigidity. That the removal of the spinal processes and laminæ can of itself interfere with the stability of the spine seems absurd, as these portions of the spine under natural conditions do not transmit the weight of the body; hence how can their removal affect a function which they do not possess?

In cases that do not require laminectomy at the Children's Hospital they apply a constant extending force by what is known as Hilliard's apparatus, with very satisfactory results. In this apparatus extension of the spine is obtained by constant traction on the pelvis by a pelvic band and counter-extension on the head by a head-band.

By the use of this apparatus in early cases of caries deformity is prevented, and prevention of deformity is a valuable result. In cases of existing deformity the apparatus is more valuable if a sand-bag is applied under the most prominent part of the back. The writer has obtained the best results with this apparatus in cases of cervical disease, then in dorso-lumbar caries, and would certainly recommend the apparatus in all cases where the deformity is not already fixed by bony changes.

There can be no doubt that a spinal curve such as exists in these cases of spinal caries is due to the patient being allowed to walk about or to lie on a bed which accommodates itself to the spine rather than the spine accommodating itself to a hard bed, in early stages of the disease. In most cases the curve is formed so gradually that it is not noticed until it is pronounced.

In private practise we seldom come across cases of marked curvature, because earlier notice is taken of the condition, and means adopted to prevent the curve becoming more marked.

Attacking a spinal abscess by cutting down on to the vertebræ themselves was suggested as far back as 1887 by Dr. Thomas Laffan at the Dublin meeting of the British Medical Association. It has strong recommendations in suitable cases. This can be done without removing both laminæ, and in the dorsal region can be done without interfering with either.

The removal of the spinous processes only with a view of rendering less noticeable an

existing deformity without attacking the actual disease is a procedure that has only its esthetic effect to recommend it. The actual removal of the caseous foci before attempting the reduction of the deformity is a more scientific procedure.

In one of the writer's cases which did remarkably well for two months, tubercular meningitis was set up by, as afterwards seemed probable, a caseating gland. At the post-mortem the amount of repair in the spine far exceeded the author's expectations. Such repair is impossible after forcible rectification when the caseous mass is left behind; so that one anticipates that the after-history of such cases will include many instances of relapse, and many cases in which the disease has run its ordinary course even if no aggravation has occurred.

#### ON OPERATION IN SOME CASES OF TERTIARY SYPHILIS.

W. WATSON CHEYNE in the *British Medical Journal* of November 27, 1897, makes some interesting observations on this subject dictated from clinical experience. He says we all know that cases of tertiary syphilis sometimes occur which are extremely obstinate to treatment by iodides and mercury, in however large doses the former are administered; and under suitable circumstances a cure may be effected by operative intervention. In support of this proposition Cheyne cites the two following cases:

Some ten years ago a man, about forty years of age, consulted him on account of an obstinate syphilitic ulceration of the cheek. The patient had acquired bad syphilis some years before, and for two or three years had suffered from a serpiginous ulceration of the cheek in front of the ear which was of a most obstinate character. He had been under careful antisyphilitic treatment since its first appearance by men of the highest authority, and although the condition improved under treatment, no sooner was it left off than the trouble reappeared. As the writer could not suggest anything better in the way of medicinal treatment, and as the trouble was limited, excision of the diseased tissue was performed, and the gap filled up by a plastic operation. The wound healed, and the disease had not recurred some years later when the author last saw the patient. The tissue was examined microscopically, and simply showed inflammatory tissue; no trace of rodent ulcer or tuberculosis; but from the

history and clinical characters there could be no doubt as to its syphilitic nature.

The second case was that of a married woman, aged forty-four, who was admitted to the hospital on April 20, 1896, with symmetrical ulcerated patches on the extensor surfaces of both forearms. The history of the trouble was that it began about a year previously, with swellings about the upper part of the forearms, which were opened. At the same time she noticed a number of swellings over the extensor surfaces of both forearms, which became red and ulcerated and soon ran together into a raised, brawny patch occupying the greater part of the extensor surfaces of both forearms, and covered with numerous ulcers. She was treated for some time at another hospital, chiefly by boracic poultices, without any improvement. In the autumn of 1895 she went into the country, also without any benefit. In February, 1896, she came under the reporter's care, and was ordered large doses of iodide of potassium and mercury, the iodide being increased up to ninety grains a day. Under this treatment improvement followed, a considerable portion of the ulcerated surfaces healed, and the patches became less prominent. After a time, however, the improvement ceased, ulceration began again, and as she was suffering much pain in the arms, she was admitted to the hospital.

The patient was a weakly, anemic woman, who had been in indifferent health for some years. She stated that after marriage she had a healthy child, then a miscarriage, and then a living child who developed, shortly after birth, snuffles and rash; in fact, from her description there could be little doubt that the child suffered from congenital syphilis. No satisfactory history of syphilis could be obtained as regards herself, but since the miscarriage her health had been bad. On the extensor surface of each forearm was an extensive red, raised, brawny patch, practically symmetrical on both sides, extending from about three inches below the olecranon to about two inches above the wrist, and almost reaching the sides of the forearm. The surface of the patch was covered with numerous ulcers, and punched-out holes varying from a shilling to a florin in size, some circular, but many of them having run together into irregular forms. The patches were very tender. The case was shown to several authorities, who, with one exception (who thought it tuberculous), pronounced it to be tertiary syphilis. There was no thin

undermined skin around the ulcers, as is so characteristic of tuberculous disease. Iodides and mercury had a distinctly beneficial effect. Microscopical examination failed to show any tubercles, and animals inoculated with portions of the tissue remained well, and did not develop tuberculosis.

As the patient was incapacitated from work, and as it had not healed under anti-syphilitic treatment, the writer determined to excise the patch on one forearm in the first instance. This was done on the right side on April 25, 1896. An incision being made all around the affected part and about half an inch beyond it, it was raised with the fat and fascia beneath, and removed. The extensor muscles were left exposed over the whole extent of the wound, which was then completely covered by skin grafts after Thiersch's method. All the grafts took, and the patient left the hospital on May 16 with the arm well. When she was admitted she was at once put on large doses of iodide of potassium, combined with drachm doses of liquor hydrarg. perchlor., and emplastrum hydrargyri was constantly applied to the left arm. Under this treatment the left arm improved markedly, the brawny swelling went down, and most of the ulcers healed. After her discharge the same treatment was continued, but very soon improvement ceased, her attendance became irregular, and in a short time the arm was as bad as before.

Patient was readmitted on November 24, 1896. The left arm was in the condition previously described, and extremely painful; the right arm was perfectly healed, with no tendency to recurrence and no imperfection in the movements of the fingers or hand. On November 25 a similar operation was performed on the left side as has just been described as regards the right. The grafts took well, and she was discharged on December 24 quite well, and has remained so since.

The writer also refers to a tongue half excised for an obstinate ulcer, which had resisted large doses of iodide of potassium, and was looked on as epithelioma, but which did not prove to be so on examination by the microscope, and in which he found another gumma in the substance of the tongue. The patient lived for several years, and had no further syphilitic disease of the tongue.

In tertiary syphilis affecting bones the possibility of doing good by operative interference is much greater and more frequent. In-

cases of gummatous bone disease with ulceration of the skin over it, he has obtained healing without recurrence by thoroughly removing the affected soft parts and chiseling away the diseased bone just as one would treat a tuberculous disease, constitutional treatment being of course continued. One has only to look at a case of syphilitic necrosis, say of the frontal bone, to understand how slow must be the cure if it occurs at all by medicinal treatment alone. Not only is the sequestrum firmly fixed in parts and very slow in separating, but the bone around is extremely condensed and the circulation in the diseased area must be very imperfect. One can thus readily understand how by chiseling away the sequestrum, the diseased bone, and some of the condensed bone, naturally without any intermission of the constitutional treatment, healing may be greatly favored. Apart from this form of bone disease, good might be done by operation in cases where there is much thickening of an individual bone with great pain, where the effect of the iodide is only temporary, and where in order to be comfortable the patient has to go on taking iodides for an indefinite period. Such cases might quite well be treated in the same way as chronic periostitis and osteitis due to other causes—namely, by cutting down on the bone, dissecting off the thickened periosteum, and freely chiseling away the affected bone.

In the opinion of many a gumma does not contain the syphilitic virus, and is some peculiar after-effect of the poison. The writer's belief is that when the virus of syphilis is discovered it will be found in gummata as well as in the earlier syphilitic lesions, though possibly altered in its character, and no longer capable of causing a general disease. The general clinical history of gummata is not unlike that of tuberculosis, and gummata often remain localized for a long time, a patient with gummata in the leg, for example, often going on for a very considerable time without the appearance of disease elsewhere. Hence the local treatment of gummata by removal in cases which will not yield to medicinal treatment, or where the patient cannot bear a thorough course of treatment, is no less worthy of consideration than the local treatment of tuberculous lesions. Iodides are admittedly only temporary remedies; unless combined with mercurial treatment no permanent freedom is certain. Indeed, in some cases iodides alone seem to have the same disadvantage as was attributed

to tuberculin, namely, that the virus is, so to speak, liberated, and after the cessation of the treatment leads to fresh lesions in the neighborhood; and the removal of the local lesions may prevent the occurrence of further lesions in the vicinity, which rather seem to spread by local infection than by fresh deposit from the blood.

In very rapidly breaking down gummata, in parts where the result may be serious, as in the palate, thoroughly clearing out the gummata might be advantageously combined with vigorous antisyphilitic treatment. In mentioning this matter of operative interference the author would in no way intermit vigorous general treatment, nor does he think operation is necessary except in a limited number of cases.

---

#### TREATMENT OF TUBERCULAR OSTEO-ARTHRITIS BY IODOFORM INJECTIONS.

DUPLAY and CAZIN (*Revue de Chirurgie*, No. 11, 1897), after experimenting with other drugs, have lately confined themselves entirely to intra-articular injections of iodoform in the treatment of white swelling of joints. Because of the pain attendant upon ethereal solutions of this product they have employed a mucilaginous emulsion containing thirty-three-per-cent. iodoform; five cubic centimeters of this mixture was employed at a dose, containing between twenty and thirty grains of the active drug. Injections were repeated twice a week; when improvement was slow every second day. In seven cases the results were very satisfactory. In the eighth case, complicated by suppurating sinuses, resection was necessary; the ninth required amputation. Results were especially good in white swelling of the knee-joint. Five patients treated for this affection were cured in from four to six months, and the cure was permanent. These patients were past the age of infancy and exhibited a local condition which apparently called for resection.

---

#### METHOD OF RENDERING THE POSTERIOR URETHRA INSENSITIVE.

SCHARFF (*Centralblatt für die Krankheiten der Harn und Sexualorgane*, 1897, No. 1) states that it has long been known that a rectal suppository will deaden the sensitiveness of the urethra to instrumentation.

Instead of using suppositories Scharff employs the various drugs in solution, and finds

that fifteen minutes after a rectal injection has been given the posterior urethra is insensitive.

For instance, in acute urethro-cystitis with imperious calls for micturition, and blood at the end of the act, he injects into the rectum five minims of:

Morphine hydrochlorate, 5 grains;  
Atropine sulphate,  $\frac{1}{2}$  grain;  
Distilled water, 3 fluidounces.

Or the same quantity of:

Ext. opium, 24 grains;  
Ext. belladonna leaves, 10 grains;  
Distilled water, 3 fluidounces.

In order to produce an antifebrile as well as an analgesic effect, Scharff employs:

Antipyrin,  
Sodium salicylate, of each  $12\frac{1}{2}$  drachms;  
Cocaine hydrochlorate, 16 grains;  
Distilled water, 3 fluidounces.

For cases in which instrumentation is painful and cocaine *per urethram* is not sufficient, Scharff injects into the deep urethra a gramme of the following solution, after he has thrown fifteen grains of antipyrin dissolved in a one-per-cent. solution of cocaine into the rectum:

Antipyrin,  $2\frac{1}{2}$  drachms;  
Cocaine hydrochlorate,  $1\frac{1}{2}$  drachms;  
Distilled water, 3 fluidounces.

The author also draws attention to the value of the faradic current in reducing the pain of the introduction of instruments along the deep urethra.—*Treatment*, Nov. 25, 1897.

#### TREATMENT OF LARGE EFFUSIONS INTO THE KNEE-JOINT.

DUMS (*Centralblatt für Chirurgie*, Sept. 18, 1897) recommends an active therapy for large effusions into the knee-joint, either by puncture or incision. Although massage, compression, etc., will in time cause the disappearance of the fluid, yet in the meantime the joint capsule has been so long stretched that a return of the affection is probable. Even when the fluid is promptly removed from the joint there is still danger of a recurrence, and the limb should be protected from strain for some time by being very gradually brought again into service. Dums' plan of treatment is as follows: As soon as the fluid is removed, a firm bandage is applied, and the limb fixed in an immovable apparatus in an extended position. At the end of a week the bandage is removed, a few passive motions made, and a starch bandage applied. One week later the patient may go about on crutches. From this time on a gradually

increasing amount of active and passive motion is allowed, and at the end of six or eight weeks a complete cure may be expected. This treatment appears tedious, but the relapses are fewer than those which follow the ordinary method.—*Medical News*, Nov. 20, 1897.

#### SOME EXPERIENCE IN THE DIAGNOSIS OF SURGICAL DISEASES OF THE KID- NEY, URETER, BLADDER, PROS- TATE, AND URETHRA.

BAYARD HOLMES (*Annals of Gynecology and Pediatrics*, December, 1897) in discussing this topic concludes as follows:

Auscultatory percussion is a useful method of examining the kidneys, and can be relied upon to determine the location and size of these organs in thin and moderately strong or fat people.

Before a nephrotomy or nephrectomy the ureters should be catheterized in both men and women to determine the competence of the remaining organ.

#### RENAL SURGERY.

OBALINSKI (*Wien. Med. Woch.*, 1897, Nos. 6 and 7) gives details of seven operations on the kidney recently performed by him, as the result of which he has arrived at the following conclusions:

Most of the symptoms and signs presented, such as pain, enlargement of the kidney, and dislocation, with simultaneous changes in the urine, lead customarily to an indication as to which of the two organs is affected. It is only in exceptional cases that it requires the use of the cystoscope to decide which ureter is passing pure and which pathological urine. It is only in exceptionally well marked and rapidly progressive cases that an accurate diagnosis and certain therapeutic indications can be obtained by means of the ordinary methods of investigation; very often, and particularly in the early stages, direct inspection by exposure or incision of the kidney must be added. If it is difficult to tell whether the kidney or another organ (for example, the gall-bladder) is affected, an exploratory laparotomy should be made; if, however, the question is simply the extent of the kidney lesion, exposure of the organ by the retroperitoneal route will suffice. The kidney is so important an organ that it should only be sacrificed when it contains some growth absolutely dangerous to the whole

organism, or when the morbid process has rendered it useless. The author recognizes only two absolute indications for nephrectomy—enlargement of the kidney by new growth or tubercle. Other conditions revealed when the organ is exposed or incised may afford relative indications. Observations made in the course of nephrectomies show that a kidney which before operation can be recognized as enlarged and hard is as a rule quite, or almost, functionless, whereby we may often get an indirect insight into the functional capacity of the other kidney. As the modern tendency is conservative and in favor of nephrotomy rather than nephrectomy wherever possible, the separate investigation of the two sides is seldom called for, particularly as Pawlik's procedure for this purpose is difficult and often uncertain. Obalinski goes so far as to say that nephrectomy is absolutely contraindicated in certain conditions, as when the other kidney can be shown to be absent, when both kidneys are affected by the same disease, when the bodily strength does not permit so radical an operation, or when the kidney capsule is tightly adherent to other organs.—*British Medical Journal*, Nov. 27, 1897.

#### CLINICAL PHASES OF EXTRA-UTERINE PREGNANCY.

CORDIER (*Annals of Gynecology and Pediatrics*, December, 1897) in a consideration of this complication makes the following deductions:

Extra-uterine pregnancy is more frequent than is generally believed by most of the profession.

When left to Nature's resources the mortality is very high, the patient dying from primary hemorrhage or, secondarily, from sepsis and peritonitis.

The diagnosis is usually easy after the rupture takes place.

The surgical mortality, in skilled hands, when done in time, is very low.

No case of ruptured tubal pregnancy is out of danger until after a good ligature has secured the bleeding points.

The abdominal route is the best and safest manner of approach in these cases.

Most cases should be irrigated properly, and drained after removing the diseased tube and liberating all adhesions.

In all abdominal and pelvic diseases these cavities should be examined most carefully before making a diagnosis.

## Reviews.

THE ORIGIN OF DISEASE, ESPECIALLY OF DISEASE RESULTING FROM INTRINSIC AS OPPOSED TO EXTRINSIC CAUSES. With Chapters on Diagnosis, Prognosis, and Treatment. By Arthur V. Meigs, M.D. With one hundred and thirty-seven original illustrations.

Philadelphia: J. B. Lippincott Company, 1897.

This book, the result of years of keen clinical observation and painstaking pathological research, demonstrates that the symptoms of disease are rarely indicative of an affection of one particular organ, but that, as a general rule, they represent a multiplicity of lesions throughout the body—lesions, moreover, which frequently long antedate a fatal issue; and it also endeavors to demonstrate that the origin of disease may be investigated without an appeal to the theory of infection as it is ordinarily understood, which theory the author evidently considers of secondary importance in our etiological studies.

Chapter II is devoted to the disease of age, which, whether it manifests itself as rheumatism in its various types, as nephritis and its concomitants, or as ordinary senile degeneration, depends upon the same pathological lesion—wide-spread, insinuating, and progressive—namely, a morbid fibrosis bearing only slight resemblance to the natural fibrous tissue of the body, being, in fact, so different from it that the author doubts whether it is properly called fibrous tissue at all.

While the idea of a physiological death is attractive, Dr. Meigs points out that it is practically impossible, because what is known as physiological decay is identical in its pathological lesions with Bright's disease, or fibrosis, or, as he denominates it, the disease of age. Although fibrosis is essentially the disease of age, it is not necessarily confined to this period of life, but may appear "in middle age, and even in youth, presenting, so far as the pathological conditions are concerned, exactly the same appearances as are found in those old in years." So-called Bright's disease of the chronic form, with its essential features of fibrosis and certain changes in the blood-vessels, especially in the intima, is the type of the disease of age, with the understanding, as has just been stated, that the period at which the body begins to show the disease of age differs greatly, and that its earliest signs as the result of inherited tendencies may begin even in the embryological state. In the pres-

ent condition of our knowledge the author believes it impossible to determine whether the blood-vessel changes antedate the fibrosis and are its cause, or whether they are its consequence; or, on the other hand, whether the fact that the two are always in company is to be considered as a mere coincidence.

The last possibility, he thinks, is in the highest degree improbable.

Having thus described fibrosis as the underlying wide-spread pathological lesion of the disease of age, Dr. Meigs proceeds in Chapter III to consider more specifically the origin of disease, and, as before intimated, calls attention to the fact that many diseases arise in consequence of latent changes which occur without producing external evidence of disturbance on the one hand, and on the other that the disease is rarely confined to one organ, and that it is necessary to make "a general survey of the whole bodily condition, and a study of the relations of various parts one with another, to advance our understanding of the origin of disease."

A parallel is drawn between the malignant diseases, cancer and sarcoma, and the fibroid process, because fibroid changes in other places besides the kidney are as much a part of this form of Bright's disease as metastatic deposits are of cancer and sarcoma, and are of just as frequent occurrence.

Reaching the subject of consumption, or phthisis pulmonalis, Dr. Meigs discusses at some length the doctrines of Laennec and Niemeyer, and comes gradually to the period of Koch's discovery of the bacillus tuberculosis, which he acknowledges at the present time throughout the civilized world is accepted as the cause of the specific new growth which is the essential pathological lesion of so-called consumption of the lungs. Dr. Meigs himself, however, denies the bacillary origin of the tubercle, and, supporting his assertion with quotations from Sir Andrew Clark, as to the existence of cases of non-bacillary fibroid phthisis, thinks if they are admitted (and, according to him, admitted they must be), the bacillary doctrine falls to the ground. Having admitted a form of phthisis not due to bacilli, it follows that it must be caused by some disordered action of the bodily organism itself—for example, inflammation—and such being the case, he regards it, with Sutton, as more logical to look upon the bacillus as a feeder on dead tissues, and not as an agent which caused the tissues to die, or to assume the morbid

condition which we call phthisis pulmonalis. His beliefs are summed up in the following quotation: "Since it has been proved that cases of consumption do result from inflammation, and since at the same time it has not been scientifically demonstrated that the bacillus tuberculosis ever is its cause in human beings, but only that the bacillus is present in the altered tissues of persons suffering with the disease, it is much more logical to believe that consumption is only the result of ill-ordered growth and disintegration of the natural component parts of the organism."

The origin of consumption is regarded as different from that of cancer because external conditions have a larger influence in producing it, but both diseases are alike in that they arise, so Dr. Meigs maintains, without the introduction into the organism of any foreign substance as their primary cause.

Syphilis, on the other hand, is a disease which in its origin is the opposite of cancer and consumption, arising "only in consequence of the introduction into the body of a specific material poison which there is reason to believe is of a nature heterogeneous from anything in the healthy tissues. It resembles cancer and consumption in that its more remote effect is a tendency to produce morbid fibrous tissue and many lesions that are identical with those common in various forms of chronic disease."

Another class of disease is constituted by the so-called exanthemata. Indeed, according to the author the actively contagious diseases, the source of which he considers beyond our present comprehension, constitute a class by themselves. Having proceeded thus far, Dr. Meigs considers it proven that the origin of disease is from two causes, extrinsic and intrinsic, and that four great divisions typified by cancer, consumption, syphilis, and the ordinary contagious diseases such as measles, may be established. With some one of these four types all known diseases may be classed.

The next nine chapters (IV to XII) are concerned with a careful pathological study of the blood-vessels, the heart, lungs, liver, spleen, stomach, intestines, kidney, and spinal cord, and represent a monument of industry and a wealth of pathological investigation.

The illustrations—one hundred and thirty-seven superb etchings and drawings—are all original and, as we learn from the preface, were made by Mr. Hermann Faber and Mr. Erwin F. Faber from sections of the tissues prepared by Dr. Meigs. Too much praise

cannot be given to this portion of the work, and author and artists are to be heartily congratulated.

The commonest disease of the arteries is thickening of the intima. The unsatisfactory character of the fibrous coat of the arteries is commented upon, and Dr. Meigs is of the opinion that it would be better to describe only two coats in arteries and veins, namely, the intima and the muscularis, and to allow the now named adventitia to be regarded as part of the perivascular connective tissue. The importance of this statement in relation to the doctrines of Gull and Sutton concerning the origin of arterio-capillary fibrosis can readily be understood.

Very instructive are the studies of new blood-vessels in morbid growths. Dr. Meigs's well known researches on the microscopical anatomy of the human heart are further elaborated in Chapter V of the present volume, and the capillaries within the muscular fibers of the heart, which he discovered, are well depicted and described. It is interesting to observe that his researches have led him to believe that compensatory hypertrophy of the heart, as ordinarily understood, has no existence, but that the enlarged heart is always degenerated and weakened.

Space does not permit more than a brief mention of the mass of interesting material which Dr. Meigs has gathered together and microscopically studied, but especial attention is directed to his researches in the pathological anatomy of nutmeg liver, the formation of the so-called new bile-ducts, the manner of the destruction of the kidney in Bright's disease, and particularly of the wide-spread lesions which are characteristic of chronic disease in general.

The concluding chapters of the book are devoted to the diagnosis, prognosis and treatment of chronic disease, and form a section of great value to the clinician.

As may be inferred from this very imperfect *résumé*, the author comes in sharp conflict with certain views which are generally accepted in the pathological world. He has studied earnestly, worked faithfully, and interpreted honestly—that is, according to his light, which reveals to him a picture meaning something very different from that which the same picture illuminated by a different light might mean to another observer. Whether the inferences which Dr. Meigs draws are always sound remains to be proven by future investigations, but no one can dispute for a moment that he has set a pace in

pathological research which must be equaled by those who intend either to follow him or to refute him. If the book accomplishes nothing else—and we believe it will accomplish very much more—it has established on a perfectly firm basis the necessity of accepting disease, especially chronic disease, as the expression of a lesion which, far from being confined to a single organ, is multiple and wide-spread.

After a careful perusal of this book the reviewer feels that it is fair to give expression to two regrets: First, the absence of control sections—that is to say, the absence of sections of arteries and other tissues taken from bodies known to be healthy, or, at least, which gave no evidence of disease before death. Such specimens can always be obtained at coroners' inquests, and they might have aided the interpretation of some of the phenomena presented by the morbid tissues. Second, the sweeping contradiction of certain accepted medical beliefs—for example, the bacillary origin of phthisis and the specific nature of typhoid fever—in the absence of any analysis of the facts on which these beliefs are based. It would seem that justice to the other side demanded this.

Time will show the value of Dr. Meigs's investigations, and he is most heartily to be congratulated upon the publication of this really splendid work, which is commended to the thoughtful consideration of all physicians. Independently of its value as a record of original thought and investigation, the book is a literary treat; the style is polished and the diction at once forceful and graceful.

G. E. de S.

AN EPITOME OF THE HISTORY OF MEDICINE. By Roswell Park, A.M., M.D. Illustrated. Price, \$2.00 net.

Philadelphia: The F. A. Davis Co., 1897.

At the present time, when every physician feels the necessity of constant study of modern works of reference and medical journals, we are too apt to overlook the fact that a thorough knowledge of the history of medicine and of the labors of our predecessors in the medical ranks will often do us almost as much good as an examination of more recent literature. The present volume had its origin in a series of lectures given in the Medical Department of the University of Buffalo by that very able surgeon and author of this volume, Dr. Roswell Park, who in preparing the text for the printer has amplified it so that we have before us a volume of 341 pages, divided into fourteen

chapters. In the first of these we find a discussion of medicine among the various ancient nations, such as the Egyptians or Chinese; then the Arabic period is discussed, and so on we are brought down to such modern times as within the last decade. In the text describing medicine during this century we find pictures of such well known medical men as Virchow and Billroth, Astley Cooper, Brodie, Rush, George B. Wood, Flint, Physick, and Agnew. In Chapter XII is a discussion of the history of anesthesia, illustrated by a picture of Morton making his first public demonstration of etherization at the Massachusetts General Hospital. The thirteenth chapter is devoted to the history of antiseptics, and the fourteenth deals with an epitome of the history of dentistry.

The book concludes with a list of names well known in medical history, and a copious index. Dr. Park is well known as a clear and readable writer, and to those who desire to obtain information and amusement in a spare hour we most cordially recommend this volume.

**DISEASES OF THE STOMACH.** By John C. Hemmeter, M.B., M.D., Ph.D. Copiously Illustrated. Price, \$6.00. Philadelphia: P. Blakiston, Son & Co., 1897.

This very handsome book consists in nearly 800 pages of useful information in regard to Diseases of the Stomach, and, in addition to dealing with the special pathology, diagnosis and treatment of this disease, it has sections on the anatomy and physiology of this viscus, another upon an analysis of the stomach contents, and a third upon Dietetics and the Surgery of the Stomach. The author tells us in his preface that his chief aim has been to furnish the practitioner with a work from which he can readily acquaint himself with all that has been done in this important branch of medicine, to fit himself to make examinations, to take advantage of new methods of diagnosis, and to treat this very difficult class of diseases rationally and successfully. The book naturally opens with chapters upon Anatomy of the Stomach, and these are extended to include also the small intestine. The physiology of digestion is taken up, including not only gastric digestion, but digestion as it is carried on in the small intestine. The influence of the bile is then studied, and details are given for the testing of the motor functions of the stomach. In this part details are also given of the experiments made by the author, and of his original methods of making tests.

In the second part there are papers upon the "Therapy and Materia Medica of Stomach Diseases," in which is a very careful consideration of dietetics and the use of various waters. There are also chapters devoted to the medicinal and surgical treatment of organic gastric diseases.

Part III, which is entitled "The Gastric Clinic," takes up a consideration of the individual diseases of the stomach.

The first point that strikes the reviewer of this volume is the exhaustive manner in which its author has studied the literature of the subject upon which he is writing, and secondly, one is impressed with the fact that its pages also contain many original observations. We think it a mistake, in view of the good original work which has been done by Dr. Hemmeter, that he has included such long quotations from various articles—such, for example, as that from the excellent research of Bensley upon the Histology and Physiology of the Gastric Glands. In connection with these quotations, however, are excellent colored plates from Bensley's research showing the minute anatomy of the stomach.

Nearly every chapter of importance is fortified by an exhaustive bibliography which frequently covers several pages, and extends over English, Continental and American literature. Tables of differential diagnosis are also found in the volume and add considerably to its usefulness.

As this is the first exhaustive work upon Diseases of the Stomach published in this country, the author of which is an American, it should receive a cordial indorsement from the profession. It is true that a manual of Diseases of the Stomach by Dr. Einhorn has already appeared, but it does not attempt to be so exhaustive in its scope. We congratulate Dr. Hemmeter upon having completed a very useful volume, which shows that he is not only a competent and original investigator, but also a skilful writer.

**THE SKIN DISEASES OF CHILDREN.** By George Fox, A.M., M.D. Illustrated by photogravure and chromographic plates and sixty other illustrations. New York: William Wood & Company, 1897.

The preface tells us that this volume consists in the reproduction of a series of illustrated articles upon certain skin diseases which are apt to occur in infancy and childhood, which appeared in the *American Journal of Obstetrics and Diseases of Women and Children* a year ago. The diseases of the skin which are treated number eighteen,

the first chapters being devoted to such frequently met with conditions as Alopecia, Ringworm and Favus, Impetigo and Psoriasis, with other chapters upon such important subjects as Eczema, Nævi, Syphilitic Skin Eruptions, Purpura and Scabies.

The photo-engravings and other full-page illustrations are extraordinarily good, and when we compare these modern methods of illustrating books with the expensive and almost futile methods of a few years ago we can but congratulate the profession and the medical publisher upon the advances which have been made. The text describing the diseases which we have named, and others of less importance, covers ninety-four pages, and is followed by a formulary which covers seventy pages. Under the head of each disease in this formulary are given various prescriptions which have been found useful by the author or others in practise.

A short index completes this very useful volume, which is printed on first-rate paper and in very handsome style.

**A HANDBOOK OF THERAPEUTICS.** By Sydney Ringer, M.D., F.R.S., and Harrington Sainsbury, M.D., F.R.C.P. Thirteenth Edition.  
New York: William Wood & Company, 1897.

The twelfth edition of this book, which appeared almost ten years ago, was a very large one, and met with a cordial reception on the part of the medical profession both in this country and in England. To those who are not familiar with previous editions we may state that this work was never intended as one which should be used as a text-book to take the place of those commonly employed in medical schools. On the contrary it is to therapeutics what Fothergill's Handbook of Treatment is to clinical medicine. It discusses the various drugs, to be sure, but it classifies them according to their clinical arrangement rather than that arrangement which is commonly followed by authors in works upon *Materia Medica* and Therapeutics. Its pages continually reveal the clinical experience and beliefs of its authors, and for this reason it proves most interesting reading to the practitioner and to the student who has time to resort to it, although the information which is given in regard to the general action of most of the remedies is too brief to supply him with the needed fundamental knowledge concerning these drugs. This is the first edition in which Dr. Sainsbury's name has appeared upon the title-page, although the names of Ringer and Sainsbury

joined together have been familiar to pharmacologists for many years. The volume concludes with a new chapter upon serum therapeutics, and by no means the least valuable, a copious and well arranged therapeutic index.

**LIPPINCOTT'S POCKET MEDICAL DICTIONARY.** Edited by Ryland W. Greene, A.B.  
Philadelphia and London: The J. B. Lippincott Company, 1897.

Although this little pocket dictionary covers 421 pages the paper is so thin that the space required in the pocket is scarcely more than that which is ordinarily occupied by the pocketbook. It is, as may be imagined from its title, a condensation of Lippincott's Medical Dictionary, which was published about six months ago, and contains all of the words commonly employed in medicine, with now and again a table, which adds materially to the value of the book. Altogether we are told that 20,000 words are defined and the methods of their pronunciation described in this little manual, which closes with a table of doses in both apothecaries' and the metric system, and which seems to us to meet every need of the student and busy practitioner; while its moderate price is a strong attraction to both of these classes of book buyers.

**A SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS.** Edited by Alfred Lee Loomis, M.D., LL.D., and William Gilman Thompson, M.D. Volume II; pp. 941.  
New York and Philadelphia: Lea Brothers & Co., 1897.

The standard established in the first volume of this System is fully sustained, if not excelled, by the second volume at present under consideration. In reviewing the first volume we took occasion to remark that it lacked to a noticeable degree the fault common to most "Systems" in the overlapping of the subjects and the varying teaching of the different authors. This favorable criticism we think applies with equal force to the second volume. In this volume we have presented to us the consideration of Diseases of the Respiratory System, Diseases of the Circulatory System and the Mediastinum, Diseases of the Blood, Diseases of the Kidneys, and Diseases of the Bladder and Prostate Gland. The different subjects under each of these principal divisions are assigned to authors well chosen for their ability and reputation in their particular specialties.

The volume opens with the section on Diseases of the Nose and Naso-pharynx, and

Diseases of the Larynx, by S. Edwin Solly. The consideration of these subjects is ably presented, and Dr. Solly is to be congratulated upon his practical and therefore valuable contribution. As introductory to the section upon diseases of the lungs and pleuræ Elbridge G. Cutler has contributed an article upon the Physical Signs of Pulmonary Disease somewhat elementary in its scope, but, possibly for that very reason, of especial benefit to the student. An article of similar nature by the same writer precedes the consideration of the Diseases of the Circulatory System and Mediastinum and adds to the value of the various articles included in the section.

The section upon Diseases of the Blood by Frederick C. Shattuck and Richard C. Cabot is, as might be anticipated from the reputation of these writers, one of the best in the volume, and is illustrated by colored plates of exceptional merit.

Pneumonia, bronchopneumonia, and chronic fibrous pneumonia are all too briefly considered, in proportion to the importance of the subjects, by Reginald H. Fitz. Indeed, to these three important affections but twenty-eight pages have been devoted. We are entitled to expect more from this writer upon these subjects. It is a matter of regret also that in the section on diseases of the kidneys James Tyson should be assigned only the insignificant space of four pages. The value of this section would have been greatly enhanced had this well recognized authority had a larger share in its creation.

The volume as a whole leaves little to be desired. It is a beautiful example of the publisher's and printer's art, and to the editors we express the hope that in the volumes to follow we may find the same painstaking and care that have done so much to make this and the preceding volume so generally satisfactory.

T. G. A.

PROCEEDINGS OF THE SEVENTH ANNUAL MEETING OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES. Held at Columbus, O., 1897. Edited by James E. Pilcher, M.D. Columbus, O.: Berlin Printing Co., 1897.

This volume of Transactions, comprising nearly 700 pages, is a convincing proof as to the value of concerted action in the study in times of peace of the medical and surgical problems likely to be suddenly presented in case of war. The technical nature of the proceedings is shown by the title of the papers. Thus Gihon contributes an address on The Status of the Military and Naval

Medical Officer; Wise writes on A Plea for the More Efficient Organization of the Medical Department on Our Ships of War; Siegfried considers The Work of the Medical Department on Naval Vessels; Craig discusses The Practical Disinfection of Ships of War; Woods writes on Some Practical Points on Antisepsis in the Navy. Then follow papers on Venereal Disease in the Navy and its Prevention, by Crandall; and the United States Navy Portable Folding General Operating Table, by Siegfried.

The first paper by the army men is upon The Identification of the Soldier, by Assistant Surgeon-General Alden; after this comes Clothing and Accoutrements for the Infantry Soldier; The Infantry National Guard Foot Dress, by Major Halley; The Military Physical Training, by Beyer; What to Avoid in Army Athletics, by John S. Kulp; Physical Training in the National Guard, by Westervelt; The Physical Proportions of the American Soldier, by Kilbourne. These papers are confined almost entirely to military subjects. Among those most to be commended are Griffith's contribution on the Effects of Bullets; Military Medical Problems, by Lieutenant-Colonel A. A. Woodhull; and Regimental Instruction and First Aid, by Surgeon-Captain Fletcher.

GRUNDRISSE DER PATHOLOGISCHEN ANATOMIE. Für Studierende und Aerzte. Von Prof. Dr. R. Langerhans. Zweite vermehrte und verbesserte Auflage. Berlin: S. Karger, 1896.

The first edition of the work under review was a small compendium for the beginner in pathological anatomy and was issued in form convenient for the pocket. The present edition has grown considerably in size and the text alone occupies 540 pages. The change is rather unfortunate, as the number of larger text-books of pathological anatomy is amply sufficient; while there has been need of a small compendium like the first edition. The increase in size has not been sufficient to allow of full discussions of certain subjects and yet has been such as to require some notice at least of all matters pertaining to pathological anatomy. In certain chapters, as for instance in that on Deformities and Monstrosities, the result has been that the articles have become little more than outlines or catalogues of names. It would have been far better to discuss a few of the more important forms of disease *in extenso*. The title of the work indicates that it is devoted to pathological anatomy. This arrangement is not strictly adhered to, as for example in

the sections treating of general etiology and of the pathology of fever; but on the whole morbid anatomy is the conspicuous feature in the book. We should have expected this from the reputation of the author, and might be disposed to admit the usefulness of a work devoted to morbid anatomy alone, though at the present day it seems unwise to separate pathological anatomy from pathology in general. The author's tendency to magnify the importance of the anatomical changes is evident in the article on croupous pneumonia, page 286, where he states: "Diffuse edema of the lungs and not the pneumonic exudate is the actual cause of death in all fatal uncomplicated cases." A clinical pathologist would have considered the importance of toxins, and would scarcely admit the justice of the statement quoted.

As far as the pathological anatomy itself is concerned, the work is highly satisfactory, except that we would have been better pleased with a more modern discussion of tumors. The author acknowledges his indebtedness to Virchow and particularly to this author's work on "*Krankhafte Geschwülste*." The only chapter in this section which he claims as original is that on carcinoma. It is apparent from this statement that the sections on tumors are somewhat out of date, though it must be confessed that much of the newer pathology is less reliable than Virchow's early work. The author has not been sufficiently careful to apportion the different articles equably. The article on sarcoma occupies about four pages; the much less important one on angiomata covers six pages. The same disproportion is observable in the various chapters, and particularly we would call attention to the scanty discussion of the pathology of the nervous system. We miss allusion to much of the newer work in this branch, and cannot regard the presentation even of the older pathology as satisfactory.

An innovation, as far as we are aware, in works on pathology is the discussion of all of the manifestations of tuberculosis and other infectious processes in one section under the heading of infectious diseases. This arrangement has been followed in clinical works for some time, but the pathologists have thus far discussed the infectious processes separately under the different organs.

The illustrations are few in number and not conspicuously valuable. On the whole the work is unsatisfactory.

## Correspondence.

### LONDON LETTER.

BY RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.  
LOND.

It is an ill wind that blows no good, and the epidemics of enteric fever at Maidstone, Lynn, and Clifton, and the smaller outbreak at University College Hospital, have been fruitful in producing a most instructive discussion at the Medico-Chirurgical Society on the prevention of the disease. Dr. Vivian Poore, who opened the discussion, girded at our public water-supplies and sewers as answerable for these epidemics. This was readily admitted by Sir Richard Thorne, who insisted that though the water and sewage systems had transformed the disease from an endemic into an epidemic foe, they had concurrently lowered the mortality from 3.7 to 1.7. This latter fact was confirmed by the statistics of the city of Glasgow, where prior to the introduction of its present water-supply the mortality from enteric fever was 510 per million as against an average of 193 per million for the last ten years. In face of these figures Dr. Poore's suggestions of the multiple modes of peripheral pollution stand as arguments not against the water carriage system, but against the abuses of those who enjoy it. Most of us have guilelessly washed out a length of typhoid intestine direct from the post-mortem room tap without a thought of infection of the water. However, *vere scire est per causas scire*, and with this caution we shall not err again. The conditions of modern life in towns necessitate a system of water carriage and of sewers, and in the case of public water-supplies, if the conscience of the water companies cannot be aroused to constant vigilance, the law must be asked to interfere for the more complete protection of the public. Professor Boyce, of Liverpool, urged that the bacteriological examination of the water should be constant, and made at various points of the supply. He himself had carried this out most effectually in the case of the Liverpool supply, of which he had established a complete and definite bacteriological flora; the accession of any fresh and unfamiliar microbe was investigated at its earliest appearance, and traced to its origin with unrelenting energy. Dr. Poore's advocacy of dry closets and daily removal of excreta by a sort of parcels-post scavenger system seemed to us a little un-

palatable; and we can hardly hope to return to that state of prehistoric simplicity, in which each member of the community shall see to the destruction of his own excreta. However capable Nature—with a big “N”—may be of dealing with healthy excreta, we have no sufficient evidence, as Sir Richard Thorne contended, that she has made any provision for the sterilization of specifically contaminated excreta. Disposal of excreta in the tillage of the soil may be practicable in rural districts, but not in urban districts, where the epidemics of typhoid fever almost exclusively occur. Dr. Davies, of Bristol, laid before the Society maps of the incidence of the late epidemic of milk-borne typhoid in Clifton. The proof of the source of pollution was demonstrative, only those houses being attacked at which a certain milk supply was received. Incidentally a point of some significance came to light, in the fact that a school which was supplied from this dairy escaped scot-free, and on inquiry it was found that all the milk was boiled before use. The masterly manner in which this epidemic was traced to its origin, and the abatement on removal of the cause, is valuable testimony to the good work that Preventive Medicine is carrying out in some of our large centers of population. Dr. Davies urged the extension of local control and supervision to the dairies as well as to the water-supplies. Another fact was satisfactorily established by the discussion: that the annual reports of our Local Government Board are a most valuable and instructive body of literature.

At the Clinical Society of London, on November 12, Mr. Tubley brought forward the results of a series of twenty-five cases in which he had treated angular deformity of the spine by immediate reduction. The cases submitted to treatment were those in which no degree or a comparatively small degree of ankylosis had occurred, carefully avoiding all in which firm ankylosis had taken place. Over and above the prevention of subsequent deformities, immediate reduction has this distinct advantage, that it is easier to fix a straight spine than a crooked one. So far from the operation being open to the risk of inducing paralytic sequelæ, Tubley found in several cases that existing paralysis was relieved; nor had he encountered any untoward results in the dissemination of tubercle. The period of after-treatment with rest and fixation of the spine should not be less than two or three years; less prolonged care was only liable to lead to

relapses. Seeing that the dangers of the operation are comparatively slight, and certainly not exceeding the mortality of the untreated cases, if we can be assured of the beneficial results of the treatment, the chief difficulty lies in the selection of the cases. Tubley summarizes the suitable cases as: (1) young subjects in whom the curvature is of short duration, is progressive, and has undergone no degree of firm ankylosis; (2) those in which local activity of the disease is manifest; (3) those free from visceral complications; (4) cases in which paraplegia existed and was not kept in hand by conservative methods of treatment. On the other hand, the chief contraindications to reduction seemed to be firm ankylosis, visceral tuberculosis, existing abscess, and curvatures of the cervical spine, where special dangers would be encountered. Cabot, however, was inclined to less caution in the selection of his cases. He was disposed to disregard the extent of the curvature, because though an extensive curvature represented the loss of a number of vertebral bodies, the resultant gap was not necessarily filled in by replacement of the vertebral bodies by new bone, but healing was then chiefly due to bony ankylosis of the posterior parts of the vertebral column. Equally, a considerable degree of ankylosis limited to the posterior part of the vertebræ could be removed by a preliminary osteotomy, so that each case could subsequently be submitted to reduction without risk of inducing paralysis. We should like more evidence of the resisting capacity of these alleged posterior bony adhesions. What weight can they sustain in the absence of the vertebral bodies? A firm and fixed curvature, whatever its degree, will be better than a straightened but infirm vertebral column.

The method of forcible extension of the spine is a revival of very ancient surgery; at any rate, it may be traced back as far as 1674 A.D., and in later times the abuses of the procedure seem to have inspired one of Abernethy's clinical lectures.

At the Harveian Society on November 4, Noble Smith stated that he considered forcible reduction of curvature due to caries dangerous and not permissible; but he himself had used the method with the greatest benefit in cases of simple lateral curvature of the spine. Even in cases where some deformity of the bones was indicated by the existence of axial rotation of the vertebræ, it was possible to restore a perfectly straight position by extension, such as could not be

effected by exercises alone. Exercises were so far valuable that they produced temporary correction of the curvature, but the constant use of an extension apparatus served to maintain the improved posture in the intervals of exercise; in this manner it is not unlikely that even deformity of bones may be rectified by the relief of pressure. It is difficult to see in what particular Noble Smith's recommendations are an advance upon the practise prevalent in every hospital, where patients are suspended from the neck and axillæ so as to correct the deformity, while a permanent extension apparatus is applied.

Dr. Herman's remarks on pruritus vulvæ at the Hunterian Society deserve notice. He recognizes five chief classes of pruritus: (1) Adventitious irritants, such as pediculi, dirt, worms, and pessaries. The treatment of such cases must obviously consist in scrupulous cleanliness together with removal of the cause; for pediculi in this region he uses the white precipitate ointment as elsewhere. We confess that we have never been able to satisfy ourselves of the part played by intestinal worms in inducing vulval and vaginal disorders; at the least it is a very rare cause. (2) Skin diseases—especially eczema, herpes, furuncles, urticaria, follicular and diabetic dermatitis. Eczema should be attacked locally with warm hip-baths, to which Wright's liquor carbonic detergens may be added; after the bath the surfaces should be powdered with boric acid. In diabetic pruritus he despairs of local treatment. In this we cannot agree with him, be it dermatitis or what not. No doubt general diabetic treatment will do much, as we have always assumed, by lowering the saccharine constituent of the urine; but equally we have found great curative value in the use of some simple protective ointment such as bismuth, bathing the parts freely with any simple sedative lotion before applying the ointment. Follicular pruritus he treats by squeezing out the contents of the follicles, and applying a germicidal lotion, such as 1:2000 corrosive sublimate. (3) Irritating discharges, such as those of gonorrhea, cancer, and senile endometritis. For these cases he suggests sedative and antiseptic washes to the vagina, followed by dusting sedative powders, such as dermatol and boric acid, on the vulva; stubborn cases will often yield to a strong carbolic solution, such as 1:7. (4) Venous congestion due to heart, lung, or liver disease. Locally these require much the same treatment as the preceding class, along with measures of relief

of the venous congestion. (5) He recognizes a purely nervous form of pruritus occurring in old women, and due to degenerative changes in the nervous system. It is of course difficult to substantiate such a causation, but we quite agree with Dr. Herman as to the futility of treatment. Temporary relief is often derived from alkaline baths, but even so after a while the irritation returns in spite of maintenance of the treatment.

At the Medical Society of London Dr. de Haviland Hall showed a man whose weight had been reduced from twenty-eight stone to twenty-two stone by thyroid treatment, along with a nitrogenous diet and avoidance of alcohol. Dr. Hall found that more than three five-grain tabloids of thyroid extract daily were ill tolerated, but we have ourselves recently given twice this amount to a young woman for obesity with no ill results. In this case, in spite of the fact that the patient was bedridden with a diseased hip, and could take no exercise at all, the weight was reduced by sixteen pounds in the course of a month. Dr. Hall noticed diuresis in his case, while in ours marked diaphoresis occurred, and the urine was somewhat diminished in amount. There can be little doubt that in some cases of obesity—in no way associated with the lipomatosis of myxedema—thyroid treatment may be markedly beneficial.

At the same meeting Mansell Moullin showed two cases in which he had used Coley's fluid successfully in the case of irremovable tumors, which beyond all reasonable doubt were sarcomatous in nature. The tumors were certainly not gummatous, and there was no evidence of their being simple inflammatory tumors. Such cases as these, taken along with the well authenticated cases of Coley himself, show that this treatment at least deserves a trial in cases of inoperable sarcoma. Mansell Moullin would not commit himself to an opinion as to the mode of action of the fluid, whether it exerted a specific remedial action, or whether it served merely to provoke inflammation. Dr. Colman was able to throw some light on this question from the post-mortem examination of two cases, which had died of intercurrent disease after treatment by injection. In one there was a large softened core in the interior of the tumor, while in the other there were cicatrices that probably marked the site of past inflammation. Incidentally also these autopsies showed that the treatment was applicable to round-celled and spindle-celled sarcomata.

## BERLIN LETTER.

BY JAMES J. WALSH, PH.D., M.D.

Professor Baginsky remarked the other day, at the Kaiser and Kaiserin Friedrich Hospital for Children, that the mortality of the cases treated in the diphtheria pavilion of the hospital for 1897 was about eight per cent. These are marvelous figures when we consider that the general statistics of diphtheria mortality in Berlin five years ago gave a death-rate of over forty per cent. Instead of the dread disease that used to carry off so many children, and that the physician was practically powerless against, it has become the proudest trophy of victorious therapeutics, no more to be dreaded now than the simplest of the so-called children's diseases.

Two things, however, remain where improvements in treatment may be counted on to bring further reduction in mortality: one is laryngeal diphtheria, the other mixed infection. It is his special care and methods in the treatment of the first which, to my mind, make Professor Baginsky's statistics so favorable. The prodromal symptoms of a laryngeal infection are carefully watched, and specially large and active doses of serum given at once and repeated several times if necessary. Intubation is done as soon as any serious dyspneic symptoms develop, for the lessened aeration of the blood is considered to decrease resistant vitality and inhibit the reaction of antitoxin against toxin by its effect on vital chemical processes.

Where intubation fails to give relief, tracheotomy is resorted to—always before the threatening symptoms have become so severe that serious results are already to be feared from exhaustion due to overstrained lungs and respiratory muscles. The after-treatment in both intubation and tracheotomy constitutes the feature of the therapeutics in the hospital. The children are allowed to breathe only an atmosphere that is thoroughly saturated with warm moisture. A special apparatus of Professor Baginsky's own invention is attached directly to the steam-heating pipes that warm the pavilion. This apparatus is constructed on the principle of a large, ordinary atomizer. The current of steam passes over the narrowed orifice of a pipe plunged in water, and so is partially condensed by the particles of water that its suction action draws up to mingle with it as it is dispersed around the room.

Instead of a little steam issuing from a

kettle there is a large jet of steam always clouding the room with moisture. The children are protected from dampness by rubber coverlets. In cases of severe dyspnea or immediately after operations the child is completely covered with rubber cloths except those parts that are necessary for breathing purposes, and a jet of steam allowed to blow over it for some time. Besides the fact that the breathing of dry, irritating air is thoroughly avoided, there seems to be a special therapeutic effect in this steam-bath. The membrane on the larynx seems to drop off sooner and easier and the absorption of toxins from the diseased spots to be stopped more readily.

As to the danger from mixed infection in diphtheria, very little but the ordinary general therapeutic measures can be used with fair hope of success. It was thought that antistreptococcic serum would be of use for this. It is undoubtedly a streptococcus that causes the most dangerous mixed infection in diphtheria, but nothing has become clearer recently in bacteriology than that under the form streptococcus one has to do with a large variety of very differently virulent and variously pathogenic micro-organisms.

A favorite experiment in bacteriological laboratories for the beginner is the repetition of Professor Paltauf's (of Vienna) striking demonstration as to the curative power of streptococcic serum. A rabbit is inoculated in each ear with a special variety of streptococcus culture; and after a time receives injections of streptococcic serum, obtained by immunizing another animal against one of the forms of streptococci employed. In both ears an erysipelatosus process begins. In one it heals as soon as the injections of the corresponding antitoxin are given; but in the other the inflammatory process goes on unaffected. The number of forms of streptococci are said to be legion.

It is true that Petruschky's work seems to have demonstrated within the year that the streptococcus erysipelatosus and the streptococcus pyogenes are the same beyond a doubt; but a review of his experiments would seem to show that all the ordinary streptococci found as parasites in man will under certain circumstances produce erysipelas; for the varying virulence of different species not to be distinguished from one another by any known bacteriological means is extremely great. Not only may what is virulent for one species fail to affect another, but the same thing holds for different individuals of

the same species, and even for different men. No wonder that there is considerable discouragement about using streptococcic serum; while it is still tried, it is usually only in extreme cases, where anything with a gleam of hope in it is eagerly reached for.

One striking thing that has come out in therapeutics over here as the result of the inability to grapple with mixed infection is the internal administration of tincture of myrrh, which many of your readers will remember was first suggested in Philadelphia some ten years ago. Dr. Stroll, of Munich, reports eighty cases with but one death treated by this method. He prescribes:

- ℞ Tincture myrrh, 4 parts;
- Glycerin, 8 parts;
- Distilled water, ad 200 parts.

He gives it every hour or every half hour in severe diphtheria cases, among which he includes all laryngeal diphtheria—a coffee-spoonful (five grammes) under two years; one to two teaspoonfuls (four to eight grammes) up to fifteen years; two to four teaspoonfuls (eight to fifteen grammes) to an adult. When the symptoms moderate the remedy is given only every two hours, and is continued for forty-eight hours (every three hours) after all membrane has disappeared. Dr. Stroll collects nearly 300 cases from the literature of the last three years, in which the remedy has been used with strikingly good success.

The principle of its therapeutic effect is founded on the phagocytic theory. Years ago Binz observed that the administration of myrrh caused a leucocytosis in which the white blood-cells were increased to four times their original number. The immediate cause of this is an excitation of the blood-making organs to unusual activity; the effect is the throwing into the circulation of an immense number of phagocytic cells ready to dispose of foreign bodies that they may encounter.

The surprise of the year in physiology and therapeutics came in the shape of Professor Munk's article in *Virchow's Archives* on the thyroid question. He absolutely denies that the removal of the thyroid in animals either necessarily causes death or inevitably leads to myxedema—the strumiprивous cachexia, so-called. He has never seen myxedema develop in animals and doubts if any one else has. He especially criticizes the original experiments of Horsley, on which much of the modern physiology of the animal thyroid is founded.

Professor Munk denies, too, that the feeding of thyroid or the grafting of the removed

gland into another part of the body ever lessens the dangers of thyroidectomy, which always remains a very serious operation. There is no question either, to his mind, of the compensatory hypertrophy of any other organ or set of organs to replace the function of the thyroid in animals which survive thyroidectomy. Professor Munk has a number of animals alive months after the operation, and has been especially successful in the case of apes, who have survived and are in good health nearly a year after careful, complete, but thoroughly aseptic removal of the supposedly absolutely essential thyroid.

The article is not altogether a surprise in medical circles in Berlin. Some months ago, at the Berlin Physiological Society, there was a very lively discussion of the matter, in which Munk put forth the views he now publishes.

Over a year ago Drs. Blumreich and Jacoby, working in Munk's laboratory, showed the utter falsity of Gley's conclusions, that the parathyroid glands hypertrophy, or rather evolute, from embryonal into developed thyroids, and take up the function of that gland when it is removed and they are left in the tissues. Some of their animals had lived absolutely without thyroids and without serious inconvenience for long periods after the operation. All of the work has been carefully done, and no time or inconvenience has been spared to do enough experiments to put conclusions beyond the realm of coincidence, so that the whole subject of the physiology of the thyroid, in animals at least, must be considered as once more debatable ground, though it was thought to be practically settled for a number of years past.

A number of medical men whose opinions were asked on the subject were very reserved, and said that time and further observation alone can tell. Professor Munk is after all an acknowledged authority on physiology and a most careful observer. The article would not have appeared in the eminently conservative *Virchow's Archives*, whose editor prides himself on his personal supervision of the material accepted for publication, save that it was considered to represent some of the best scientific thought of the day. Professor Virchow himself is said to have personally made the autopsy of some of the apes that had survived thyroidectomy for months, and to have found no vestige of thyroid tissue remaining to account for the survival.

The recent Leprosy Conference here

seemed to come to the conclusion that the most effective therapeutics of the disease was the administration of mercury in somewhat the same way as in syphilis. Good effects almost invariably follow its use, but discouraging relapses come, and these, as in syphilitic recurrences, are to be treated by a repetition of the course of mercury. As somebody remarked not long ago with regard to actinomycosis, the only cured cases in the literature seem to be those in which a mistaken diagnosis of syphilis was made and mercury administered. Bacteriologists have lately been describing certain forms of the bacillus of tuberculosis which developed in the tissues with the rosette form, each of the rays having the clubbed end which has hitherto been considered so characteristic of actinomycosis. The same appearance of the lepra bacillus was shown in a number of beautiful specimens during the Leprosy Conference. There would seem to be a closer relationship of form in the producers of the infectious granulomata than has hitherto been imagined, and a more intimate association in their inhibition by a certain class of drugs than has been considered to exist. Whether there is in this a therapeutic law of wider application is occupying some attention from therapists over here now. Where so much must depend on empiricism, a law even of limited application would be warmly welcomed.

#### THE TREATMENT OF RHINITIS.

To the Editor of the THERAPEUTIC GAZETTE.

DEAR SIR: I append a formula for the general practitioner in the treatment of acute or chronic rhinitis and kindred inflammations.

Of course nasal obstructions, from whatever cause, and specific affections should be differentiated from catarrhal conditions, and operative measures or constitutional treatment instituted before local medication is to be considered.

I have become convinced that aqueous medicaments or dry powders applied to the mucous membrane of the upper air passages are neither curative, nor even palliative of morbid conditions. Consequently I have been trying medicated oleaginous preparations.

Wishing to get the effect of creosote I tried in vain to obtain a satisfactory unctuous solvent for it. But when I tried guaiacol the end was attained.

The formula which I have evolved is pleasant to use and is followed by the most

gratifying results in both atrophic and hypertrophic rhinitis. The treatment must be protracted, as the antrum, ethmoid cells and frontal sinus are usually involved and the healing process has to extend by continuity.

The medicated oil remains in contact with the tissues for some time; much of it is absorbed. It is antiseptic; it protects, depletes, soothes, stimulates, and heals. It should be applied every three hours or as often as the patient's occupation and habits will permit.

The "Whitehall & Tatum Vaseline Atomizer" is the most satisfactory instrument with which I am familiar for making the application:

- B Guaiacol, 1 drachm;  
Menthol, 40 grains;  
Cocaine hydrochlorate,  
Camphor, of each 20 grains;  
Glymol, 4 ounces.

M. Sig.: Use in atomizer, spraying nose and throat every three hours, or more often if possible.

THEODORA T. PURKITT, M.D.

WILLOWS, GLENN CO., CALIF.

#### A SUGGESTION TO BE USED IN ABDOMINAL INCISION.

To the Editor of the THERAPEUTIC GAZETTE:

SIR: In performing laparotomy I have noticed that after the abdominal incision has been made it frequently occurs that from the constant introduction and manipulation of the fingers through the incision the peritoneum becomes separated to a greater or less extent from the muscular tissue; and appreciating the fact that several complications can arise from this condition of affairs, the idea suggested itself to me to introduce a stout ligature through the center on either side of the incision about half an inch from the margin of the wound, this ligature being first tied snugly, and a loop of from four to six inches allowed to remain beyond the first knot. We accomplish by this procedure two results: first, we prevent the separation of the peritoneum from the tissues overlying; and second, we have two retractors which take up no room and cause less traumatism than the ordinary metal retractors. When the operation is completed the ligatures are clipped and removed, and the wound brought together according to the method adopted by the surgeon.

Yours truly,  
HENRY J. SCHERCK, M.D.

**FOUR CASES OF STONE IN THE BLADDER, WITH HYPERTROPHY OF THE PROSTATE GLAND, WHERE POSITIVE DIAGNOSIS WAS IMPRACTICABLE UNTIL DOUBLE CASTRATION RESULTING IN ATROPHY OF THE PROSTATE RENDERED THE PASSAGE OF A STONE-SEARCHER POSSIBLE.**

BY ORVILLE HORWITZ, B.S., M.D.,

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College; Surgeon to the Philadelphia Hospital and State Hospital for the Insane; Consulting Sur-geon to the Hayes Mechanics' Home.

The result of a trial for malpractice of a prominent physician of Baltimore induces the writer to lay before the profession the his-

tories of four cases of double castration, undertaken with a view to producing atrophy of the prostate gland, in order to make an examination of the bladder practicable, and to determine the existence, or otherwise, of urinary calculi.

These cases may possibly be of interest to the profession, as they in a measure demon-strate that in some instances positive diag-nosis of the existence of stone in the bladder is impossible where hypertrophy of the pros-tate exists, especially if the middle lobe be so much enlarged as to render the passage of the stone-searcher impracticable, unless a supra-public cystotomy or a double castration be resorted to; the latter operation, it is now conceded, causing atrophy of the hypertro-phied gland.

When the enlarged gland has sufficiently dwindled, the stone, if it exist, can be readily located and extracted by suprapubic cystotomy, or crushed by lithotripsy.

A brief history of the cases is here presented:

**CASE I.**—S. A., seventy years old, broker, had been suffering from symptoms of cystic stone, which gradually intensified, for the past five years. When first seen he stated that he voided his urine many times during the day and night. He experienced great pain at the meatus urinarius at the termination of each act of micturition. The urine often contained blood, which at times was passed after urination. The urine was cloudy, offensive, with an alkaline reaction, and contained a small quantity of albumen, with pus, blood-corpuscles, and crystals of phosphates and oxalates. The percentage of urea was low. Examination per rectum revealed an enormously hypertrophied prostate. Many attempts had been made to pass a stone-searcher, but without success. The only instrument that could be introduced into the bladder was a small-sized rat-tail rubber catheter, which was passed with difficulty. When the catheter was introduced the bladder was found to contain five ounces of residual urine. The capacity of the viscus was six and one-half ounces. The patient's sexual functions had long been lost. He was told that he was probably suffering from stone in the bladder, but that it was impossible to make a positive diagnosis until the enlarged prostate, which caused the obstruction, had been reduced in size. A double castration was advised. His consent having been given, the operation was performed. Two weeks later a stone-searcher was readily passed, and the existence of calculi easily detected; these were removed by the operation of suprapubic cystotomy, and the patient made a rapid recovery.

**CASE II.**—L. T., sixty-five years old; mariner. History precisely similar to Case 1. The obstruction produced by the enlargement of the prostate permitted the passage of a very small Mercier catheter only. Double castration was performed. Fourteen days after the operation a stone-searcher was readily introduced, and a large-sized calculus was found, which was removed by suprapubic cystotomy. The patient made a rapid and uneventful recovery.

**CASE III.**—G. C. B., sixty-two years old; manufacturer; affected with hypertrophied prostate. In addition to the usual symptoms

he complained of great pain in the glans penis, especially after urination. He frequently passed blood before, during and after the act of micturition. Pain and hemorrhage were increased by riding over rough roads. Had had two attacks of retention of urine. The middle lobe of the prostate was found to be greatly enlarged. A stone-searcher was introduced with difficulty. Owing to the enlargement of the middle lobe an exploration of the bladder was not possible. The sexual powers of the individual were completely lost, and he willingly gave his consent to the performance of a double castration preliminary to cystotomy. Ten days after the operation the stone-searcher was readily passed, and two good-sized calculi were found in the pocket posterior to the prostate, and were removed by a suprapubic operation. The patient left the hospital one month after entering the institution entirely relieved.

**CASE IV.**—H. Q. M., seventy-one years old, retired merchant, stated that he had had "trouble with his bladder" for the seven years preceding his application for treatment. He complained of pain in the head of the penis, neck of the bladder, and over the pubes, after passing water. Had frequent attacks of hematuria, and one attack of ischuria. The flow of urine from the bladder was very difficult to start. The urine was cloudy, offensive, alkaline, and contained albumen, pus, leucocytes, and crystals of phosphates and oxalates. The prostate was very much enlarged. The only instrument that could be introduced into the bladder was a very small hard-rubber English catheter. Double castration was performed, and fifteen days after the prostate had sufficiently shriveled to allow of the introduction of a stone-searcher, when a calculus was readily located. It was small and was easily crushed by the use of Forbes' lithotrite. Patient made a slow but complete recovery.

In each of these cases there was marked obstruction of the urethra, due to senile hypertrophy of the prostate, complicated with chronic cystitis, with symptoms of prostatitis and stone in the bladder. In no case was it possible to make a positive diagnosis of stone; in but one could the stone-searcher be introduced, and then, owing to the great enlargement of the middle lobe, it was impossible to utilize the instrument for the purpose of exploration.

The existence of a calculus was suspected in each case, and the patients were distinctly

informed that double castration was but a preliminary operation.

Two of the individuals were sent to me by their respective family physicians, with a diagnosis of stone in the bladder; in neither had hypertrophy of the prostate been suspected, no physical examination having been made. The two others were referred to me as cases of "obstructive" hypertrophy of the prostate, the complication with vesical calculus not having been suspected.

A study of the history of the cases here submitted would seem to warrant the following conclusions:

That in cases of hypertrophy of the prostate, where enlargement is so great that a stone-searcher cannot be passed, or if it can be inserted, a thorough exploration of the bladder cannot be made, a positive diagnosis of calculus is not feasible.

That where the hypertrophy is so great that a positive diagnosis of stone in the bladder cannot be made, a double castration is an entirely justifiable operation as a preliminary measure to insure shrinkage of the hypertrophied gland, provided the patient has already lost his virile power, and is otherwise a proper subject for the operation.

That a surgeon is not to be held blame-worthy if he is unable to say positively whether a vesical calculus does or does not exist, if the entrance to the bladder is obstructed by the condition of the prostate to such an extent that a stone-searcher cannot be introduced, or if inserted, cannot be properly utilized to explore the organ, or if the existence of a calculus cannot be detected by resorting to the *x*-ray. (In this connection it may be remarked that two of the four cases whose history has been recounted in this paper came under the writer's care after the great discovery of Roentgen had been announced to the world, and that this method was used as a means of diagnosis, but failed in each instance.)

That in all cases of hypertrophy of the prostate, where exploration of the bladder by the stone-searcher is either impossible or nugatory, and where double castration is recommended, the patient should be advised of the possibility of the existence of a vesical calculus that can only be detected with certainty after the gland has become sufficiently atrophied to allow of the passage of the sound. Should a calculus be present it can be readily removed by a subsequent operation.

## PUERPERAL MASTITIS.\*

BY J. A. MURRAY, M.D.,

Member of Pennsylvania State Medical Society and American Medical Association.

I have selected this subject because it is one of the most important diseases we are called upon to treat, and one which is, to a very large extent, preventable if early precautions are taken. A lack of success in the treatment of this disease may greatly mar one's reputation. This is especially true if the case be a primipara, and singularly enough it is in this class of cases that inflammation of the breast mostly occurs. There are few things that bring more condemnation upon the young practitioner than to have the young mother's confinement followed by mastitis with resultant mammary abscess, and perhaps destruction of the breast.

One eminent authority claims that the disease occurs in one-fourth of all child-bearing women during the period of reproduction; and the fact that there is so very little written about this condition in most of our textbooks has led me to bring the subject before the Society with the hope that it may aid some of us in its prevention and treatment.

In this article I will only speak of its cause, symptoms, and treatment.

It was long believed and taught that puerperal mastitis was due to an engorgement of the gland with milk; but though there is still some uncertainty about what effect "milk stasis" has on the production of mastitis, the generally accepted theory of pathologists and bacteriologists is that the condition is of bacterial origin.

Although engorgement of the breast with milk no doubt acts as a predisposing cause, especially in that form where the parenchyma of the gland is involved, it seems to have been proved that inflammation followed by pus formation cannot occur without the introduction of the pyogenic cocci—the microbes of suppuration. While admitting that "milk stasis" acts as a predisposing cause, there can be no doubt that the important factor in its production is infection from without.

If antisepsis has proved nothing else, it has convinced the obstetricians of the world that aseptic and antiseptic treatment directed to the breast has greatly reduced the frequency of this disease. The most frequent point of infection is through an abraded or fissured

\*Read before the Clearfield County, Pa., Medical Society.

nipple, and the source of the infecting micro-organism is the child's mouth, patient's and nurse's fingers, or unclean appliances used about the breast, such as unclean linen, dirty nipple shields and breast pumps. It has not yet been proved whether the germs enter the breast through the lymph-channels or the milk ducts. Some authorities contend that the microbes of infection enter both ways, and to decide which is correct is no easy matter. So far as the treatment is concerned it makes but little difference, except when massage is used, and in this respect it is very important to make the differential diagnosis. This point will be made clear when speaking of the treatment.

In connection with the etiology and pathology of mastitis it must not be forgotten that some authorities put forth the claim that the disease is also due to micro-organisms in the mother's blood, which have been absorbed from some abrasion, tear or injury of the parturient canal or genitalia; to decomposing clots or placental tissue which have been retained in the uterus. It has also been known to follow phlebotic infection and inflammation. I have seen one case where a mammary abscess followed a severe phlebitis which practically destroyed the whole breast.

There are three principal varieties of the disease, viz., the glandular or parenchymatous, subcutaneous, and subglandular—the latter belonging to the connective tissue variety.

I will only dwell briefly upon the symptoms, except when I differentiate between the different forms of the disease, which is quite important with regard to treatment. The different varieties of mastitis are all accompanied by the signs of inflammation. At first there may be only uneasiness or soreness of a part of the breast. This will shortly be followed by chilliness or a distinct rigor; then elevation of temperature, often reaching as high as 103° to 105° F.; increased pulse-rate, pain, tenderness of one or all of the lobes, which soon become indurated, followed by a reddened skin over the diseased area. Since the glandular or parenchymatous variety is by far the most frequent and the one most amenable to treatment, I will describe the symptoms more fully and mention one distinctive differential point. This is important, since it is the subcutaneous and subglandular variety which mostly results in pus formation and mammary abscess. In the glandular variety, by careful examination you will be able to distinguish one or more distinct, hard, circumscribed, tender nodules, due to milk stasis, in

this portion of the breast. The skin overlying this may be only faintly reddened. The pain produced by manipulation is not so severe as in the other varieties. The temperature goes very high, often reaching 105° F. If the disease is not aborted at this stage the milk undergoes chemical changes; sugar is converted into lactic and butyric acids; the casein is coagulated, and in it great quantities of bacteria are found. The micro-organisms now infiltrate the connective tissue surrounding the acini of the glands, and the disease rapidly passes into the interstitial variety, complicating it with the glandular.

It will, however, sometimes occur that the connective tissue between the acini of the gland will become affected almost simultaneously with the acini themselves; in such instances it will be impossible to make a differential diagnosis. In these cases the treatment should be directed to the parenchymatous variety, which will be described later. In the connective tissue variety, which is less frequent, the interstitial connective tissue around the acini undergoes an inflammatory condition and the patient will complain of a very painful spot, which is not so well outlined as in the glandular form. The characteristic nodule of the glandular form is not so apparent. The pain is generally much more severe if manipulation or pressure is made upon the breast. There is a more gradual elevation of temperature in this form. By a careful examination it will be found that the nipple or areola is eroded, fissured, or macerated, or that they have previously been sore. The skin will early become reddened, shiny, and edematous, and this will generally correspond with that portion of the breast where the nipple or areola is fissured or eroded. This form generally goes on to an early pus formation and mammary abscess, regardless of early and persistent treatment. This is more especially the case if the nipple is much inflamed and does not quickly yield to treatment.

The first consideration is prophylactic treatment, which should begin during the last months of pregnancy, especially in primiparae, and consists in putting the nipple in the most favorable condition for nursing. The pressure of tight clothing over the breast is contraindicated in the latter months of pregnancy, because it causes retraction of the nipples. For one month before labor the nipple and breast should be treated by mild antiseptic washes daily to remove all seba-

ceous materials. Astringents and alcoholic applications should not be used. They harden the cuticle and thus predispose to fissures. The best method after daily antiseptic cleansing is the application of warm cacao butter; this makes the nipple supple and flexible, and in most instances will give good results. The prospective mother should also be taught to draw out small and retracted nipples and treat them as above stated. She should observe strict rules of cleanliness during the whole period of lactation.

The milk should not be allowed to accumulate in the breasts. After the child has nursed the breasts should be cleansed with boric acid or bichloride solutions, followed by the application of cacao butter, which must be washed off with sterilized water before the child nurses again. To prevent milk stasis or engorgement the child must be taught to nurse early. If it cannot use all the milk, it is best to draw the extra quantity by massage, being careful to always stroke the breast in the direction of the milk ducts; this if properly performed is much better than any breast pump, which is often unsatisfactory and injurious. If there is hypersecretion of milk the quantity can be lessened more surely by compression than by any medicinal remedies yet discovered. This is best accomplished by placing a heavy layer of cotton over the breast and applying a binder. It is always advisable to cut a hole in the cotton and thus save compression of the nipple. If this does not sufficiently lessen the hypersecretion, it is wise to combine with it belladonna ointment or plaster over the breast, and saline purgation for its derivative action. The child should be taught from the very first to nurse at regular intervals of two or three hours. It should not be allowed to nurse more than fifteen minutes at a time, longer periods causing maceration of the nipple and destruction of the epithelium, which will afford a pathway for the ingress of bacteria.

Any macerations, erosions or fissures of the nipple or areola must be treated antiseptically at once, after which some bland ointment must be applied. Probably the very best treatment for fissured nipples is to paint them with a five-per-cent. solution of cocaine and then touch the whole fissured tract with a fine point of nitrate of silver stick. If the nipple is too painful to permit nursing, a nipple shield may be used with good results. The pain from nursing is often relieved by painting

with a weak solution of cocaine and then coating it over with ethereal collodion or compound tincture of benzoin. Notwithstanding all the foregoing measures and precautions, the gland will sometimes go on to inflammation. It will then be necessary to put the breast to rest and take measures to relieve engorgement and lessen the tension and blood-supply. If the nipple is sore or abraded, it is always best to remove the child from the breast and thus favor healing of the nipple, lessen the pain and suffering, and decrease the secretive activity of the gland. This is also a wise precaution for the health of the infant, which may become ill from nursing milk charged with inflammatory products, and perhaps pus.

If we are now able to decide positively that the inflammation is of the glandular variety, then it is our duty to empty the gland by massage, combined with the breast pump, remembering the latter instrument only removes the milk from the lactiferous ducts in close proximity to the nipple; hence the importance of massage to facilitate the passage of milk from the acini of the gland. Having emptied the breast, we must now take measures to prevent large reaccumulations, which is best accomplished by compression, in the manner described for hypersecretion. At the same time we should use large derivative doses of saline cathartics.

After the tension of the breast has been relieved by the breast pump, massage, and compression, we should place an ice-bag on top of the binder over the most sensitive portion of the breast. This will tend to lessen the overdistended blood-vessels, relieve pain, and check the activity, multiplication and growth of the various micro-organisms. The ice-bag should be used continuously till the pain is relieved and temperature falls. Should the ice-bag prove ungrateful to the patient, it will be better to place cotton compresses saturated with lead-water and laudanum upon the breast and cover this with a rubber dam, and over this apply the binder. Of course it must be remembered all the foregoing remedies are useless if the case when first seen has gone into beginning pus formation, as then we should direct our attention to an early evacuation of the pus according to the directions that will be given later.

When the inflammation is of the connective tissue variety, subcutaneous or subglandular, the treatment will differ from that just described. Compression should not be used.

The breast should be supported by a Murphy binder. Massage, so useful in the parenchymatous form, should not be attempted, as it is sure to increase the inflammation. We must now resort to lead-water and laudanum, saline cathartics, and extract of belladonna; glycerin spread over the breast is often very useful, but we must watch its physiological action lest too much be absorbed. It is in this class of cases that we will mostly discover abrasions, macerations and fissures of the nipples, which must be treated energetically and quickly cured if we are to avert suppuration. But in spite of all we can do this variety of inflammation will sometimes result in suppuration. We will now have a mammary abscess. To discuss the different forms of this condition and their treatment would occupy far more time than is allotted me for the reading of this article. So in a general way I will only state that all forms of mammary abscess, as well as any other pus cavity, should be evacuated the moment we are sure there is suppuration.

In opening these abscesses the incision should always radiate from the nipple in the direction of the lacteal ducts. If the abscess is superficial we may freeze the part with ethyl chloride and open under antiseptic precautions. If it is deep or post-mammary, the patient should be anesthetized, and after the skin and fascia is laid open we should go down with a grooved director. When we have located the cavity it is better to open it up with a dressing forceps sufficiently to admit a finger. If more than one cavity exists, they are all to be opened in the foregoing manner. By this method there is no danger of opening up the milk ducts, which often results in milk fistulæ which are difficult to heal. After the pus is thoroughly evacuated the cavity must be well irrigated with a warm two-per-cent. creolin solution or a weak solution of bichloride of mercury. The cavities and openings should then be packed with sterilized or medicated gauze, followed by antiseptic dressing and a firm bandage. After twenty-four hours this should be removed, the cavity again irrigated with a solution of hydrogen peroxide, strips of gauze placed in the drainage tracts, and a firm bandage applied. This is left for from twenty-four to thirty-six hours, when it is removed and irrigated again, an antiseptic dressing applied, and over this compression.

The foregoing treatment will generally result in cure in a very short time unless it be a post-mammary abscess, when more radical measures will be necessary, such as curetting

the sinuses with a sharp curette or partially dissecting the gland from the walls of the chest, curetting the suppurating surfaces, and then suturing the breast in position again; the freshened surfaces, where the sinuses or cavities existed, being sutured or effaced with catgut ligatures. During the treatment the patient should have nourishing diet and ferruginous and bitter tonics. Stimulants will be found valuable in some cases.

In the preparation of this paper I have drawn to a considerable extent, on treatment, from an able article by Dr. Richard Norris, of Philadelphia, for which I return thanks.

#### *DELAYED RESOLUTION IN PNEUMONIA, AND ITS TREATMENT.\**

---

BY ALFRED STENGEL, M.D.,

Instructor in Clinical Medicine, University of Pennsylvania;  
Physician to Philadelphia Hospital, the Children's  
Hospital, etc.

---

The pathology of croupous pneumonia is so well understood that I need not allude extensively to it. There is, however, one important point to which reference should be made, and that is the time relation of the crisis or decline of fever and other marked symptoms to the actual resolution of the disease in the lungs. To me the phenomena of the crisis are among the most strange symptoms of the disease. It seems well-nigh inexplicable that a patient with a consolidated lung should pass in the course of an hour or a few hours from the condition of extreme dyspnea, high fever and general nervous excitation, to one of normal temperature and general tranquillity, notwithstanding the fact that the lesion in the lung has not apparently changed in the slightest. We are all of us too prone to regard the resolution of the lung as more or less concomitant with defervescence. In typical cases of croupous pneumonia the temperature declines before the processes of resolution have begun, or at least before they have made any considerable progress. Careful examination reveals the fact that there is a decline in dulness two or three days after the crisis, but at least several days invariably elapse before there is extensive resolution even to the crude test of percussion.

Pathologically speaking resolution may fail on account of untoward changes in the diseased area or because of mere delay in the

---

\* Read before the Section on Internal Medicine of the College of Physicians, Dec. 13, 1897.

ordinary processes. In the former instances the disease may terminate in abscess or necrosis of the lung, or in interstitial pneumonia (fibroid pneumonia). In the latter instances, after a more or less tedious course complete resolution finally takes place. While I believe it possible that these long delayed cases may be wholly normal in their histological course, I am convinced that in most instances there is at least some interstitial thickening of the septa and connective tissues generally which causes the greater delay in resolution. Termination in fibroid pneumonia of great extent or intensity is very unusual, and it is not my present intention to deal with such cases or with the termination in abscess or gangrene. I desire to limit my remarks entirely to instances in which there has been delay on account of moderate interstitial thickening, or, if such be possible, on account of mere sluggishness in the normal processes.

Delay in the resolution, as I have defined it, occurs more frequently in irregular pneumonic conditions, especially in such as are characterized by proliferative cellular processes—cellular pneumonia according to the classification of Buhl. Instances of this kind are met with among the pneumonias complicating infectious diseases and Bright's disease, and in secondary pneumonias following embolism. Other cases occur in the aged and in persons reduced greatly in vitality. The causes of delay in resolution in such cases no doubt vary in different individuals. Massive exudates are probably more difficult to absorb than moderate ones; and in any case weakness of the respiratory movements probably plays a part. Poor circulation and a weakened heart are further contributory conditions. Frank croupous pneumonia of young persons rarely shows any tendency to delay.

I wish now to sketch hastily the clinical features of a few instances. The first three are cases of pneumonia secondary to gynecological operations, and were most likely instances of embolism followed by pneumonia.

CASE I.—Miss M. A. T., aged twenty-eight years, was admitted to the University Hospital May 11, 1896. During the last ten years she had suffered with dysmenorrhea and pain in the back, and during the last two years she had complained of paroxysmal pain in the left iliac region, increasing backache, headache, and other nervous disturbances. There was a family history of phthisis, but

she herself had been generally in good health. Gynecological examination showed a retroflexed and retroverted uterus with a fibroid tumor the size of a pea in the right cornua. Celiotomy was performed on May 15 and the uterus attached to the abdominal wall. Recovery from the operation was prompt and the wound healed by first intention, but on the 20th she began to complain of pain in the right side and suffered with slight cough; this continued for several days without much aggravation and without definite physical signs. On June 1 the pain increased and she became distinctly more uncomfortable. Physical examination now discovered indistinct dulness at the right base posteriorly, and the patient expectorated slightly blood-tinged sputa. During the next several days the dulness became more distinct but not absolute, and bronchial breathing was confined to a small area. The disease continued with slight fluctuations during several weeks, the patient's general condition never being alarming in the least degree, but blood-tinged expectoration occurred now and then until shortly before her discharge from the hospital. Her general strength improved considerably, but the dulness never disappeared entirely, and the breathing, though no longer bronchial, remained harsh in expiration. During the height of the disease carbonate of ammonia, strychnine sulphate and whiskey were administered freely. On June 12 iodide of potash was ordered and was continued until her discharge from the hospital several weeks later.

CASE II.—Mrs. S., thirty-seven years old, was admitted to the University Hospital April 12, 1897. She had been married nineteen years and was the mother of two children, the youngest being twelve years of age. She had been in good health since the birth of her first child eighteen years ago. On admission to the hospital she was decidedly anemic in appearance, and was brought in in the ambulance looking as if she had been ill in bed for several weeks. She gave a history of having suffered with pain over the entire lower abdomen and as high up as the umbilicus. This was not severe, though continuous, and she complained of a bearing-down sensation in the back, with profuse leucorrhea. Ten days before admission she had been taken with sudden pain in the upper thigh and calf of the leg. This occurred during the night, and was followed at once by swelling of the leg. The limb was

slightly swollen on admission. Her family history was good, though a sister died of phthisis. The gynecological examination showed bilateral laceration of the cervix, and dislocation of the uterus towards the right. Tubo-ovarian disease of the left side the size of a baseball was discovered, and a smaller mass similar in character on the right side. Celiotomy was performed April 16, 1897, and a large tubo-ovarian abscess with adhesions was discovered on the left side. Both tubes and ovaries were removed. In the operation several ounces of pus escaped into the abdominal cavity, and a drain was therefore inserted. On the 19th of April the drain was removed and a tube was inserted instead. On the 25th the tube was removed.

On June 20 the patient was suddenly seized with severe pain in the base of the right lung, and was found in a condition bordering on shock. The breathing in the area indicated was harsh and accompanied by friction sounds and fremitus. The temperature rose to  $100\frac{1}{2}^{\circ}$ . Stimulants were administered and a strong mustard poultice applied.

Subsequently dulness developed and expectoration of a rusty character followed. In a few days hemorrhagic expectoration made its appearance, the sputa at times being almost pure blood. The patient was extremely weak, pulse irregular and feeble, and the respirations were rapid. After five days the temperature declined from the moderate elevation ( $99^{\circ}$  to  $100^{\circ}$ ) to the normal, and remained practically at the normal until her discharge from the hospital. Resolution of the lungs did not occur as is customary in pneumonias, and the case continued almost unchanged for at least two weeks after the temperature had first declined. There were, however, occasional elevations to  $99^{\circ}$  or more. She was ordered stimulants and tonics and directed to breathe deeply several times during the day. The case resulted in complete resolution after one month's duration.

CASE III.—Mrs. M., aged forty-two, had been married twenty-five years. She had had no children. She was admitted to the University Hospital March 2, 1897, complaining of frequent and painful micturition of some years' duration, and with dysmenorrhea and menorrhagia of later origin. There was a feeling of weight and bearing down, and she suffered with headaches and profuse leucorrhea. The urine was normal. The patient had always been in perfect health until the present trouble. The family history

was negative. A fibroid tumor of large size was discovered in the abdomen, and for this celiotomy was performed. The uterus, tumor, tubes and ovaries were removed. The vessels were ligatured after removal of the mass and the abdomen closed without draining. For several days the patient's condition was satisfactory, though the pulse was irregular and rather rapid. Then there was sudden pain at the base of the left chest with indistinct dulness and signs of pneumonic consolidation. There was little expectoration, and this was not hemorrhagic. The temperature at first declined, as had the other symptoms, but subsequently reached a greater elevation than at first. The pulse and respirations became exceedingly rapid, and the patient succumbed after ten days.

The autopsy showed the following conditions: The heart was exceedingly small and flabby. The endocardium and valves were normal, but the myocardium was brownish in color and evidently degenerated. At the root and base of the left lung was found an area of consolidation involving a considerable portion of the lower lobe. This was hemorrhagic in the center and firm; more decidedly pneumonic in the peripheral portions. Throughout there was evidence of advancing organization, as far as could be judged by the macroscopic appearances.

I have reported these three cases as types of pneumonic conditions seen after gynecological operations or in the puerperium. They represent a form of embolic or thrombotic pneumonia that has come under my notice a number of times and has sometimes caused me a great deal of anxiety. Two previous cases (one after ventral fixation and one after some other gynecological operation) and two subsequent cases in puerperal women resembled these closely in the irregularity of development, in the incompleteness of the pathological development, and three of the four in the tediousness of resolution.

A different class of cases may be illustrated by the notes of the two following cases:

CASE IV.—An old man, a patient under my care at Blockley Hospital, presented general arterio-sclerosis and damaged kidneys (pale, watery urine, small trace of albumen, fine granular casts). One morning he was found exceedingly feeble, and the nurse, taking the temperature, found it to be  $103^{\circ}$ . The pulse was rapid and the respiration a little hurried. Physical examination revealed a moderate degree of dulness at the left base, with fine subcrepitant râles and semi-bronchial breath-

ing. During the subsequent forty-eight hours the dulness extended and eventually involved the lower lobe completely. Stimulants were freely administered, and to our surprise the patient gained in strength and the fever declined after seven days' duration. Subsequently the temperature became irregular, rising at times to  $102^{\circ}$ , but generally remaining about normal or subnormal. The lung, however, did not show signs of resolution for two or two and a half weeks. Tonics were administered freely and iodide of potassium given for a week without notable effect. Finally blisters were applied and seemed to be beneficial, as the evidences of resolution followed promptly. A month after the decline of the temperature the chest gave no evidences of the pneumonia.

CASE V.—The following notes were made: J. R., aged forty-five years, white, a salesman, was admitted to Blockley Hospital June 9, 1896. Previous history showed that the patient had had the common diseases of childhood; rheumatism three years before admission; specific infection twenty years previously. He used alcoholics and tobacco excessively. Cough for past year; subject to colds. His present condition: a fairly well developed man; chest, some depression under right clavicle, restricted expansion over left side; respirations chiefly abdominal. Left base, increased fremitus and slight dulness. Vesicular murmur harsh; pleural friction. Cough hard and

dry. He gave a history of a chill a few hours before admission. Temperature  $102^{\circ}$ , pulse 80, respirations 28; face flushed; skin dry; slight expiratory groan.

June 10, 1896. Respirations increased; temperature high; cough severe, slight blood-tinged expectoration; increased vocal fremitus; dulness over left base, especially along axillary border. Restricted breathing; a few crepitant râles (scarcely any air seems to enter this portion of lung).

June 11. Temperature  $101^{\circ}$ , respirations 30, pulse 100. Dulness marked in left lower lobe; bronchial breathing; bronchophony; whispered pectoriloquy; expectoration rusty; diplococcus found.

June 12. Temperature  $104^{\circ}$ , pulse 49; complains of severe pain in side; bradycardia, pulse 49.

June 17. Temperature normal; but few râles in chest, feels easier.

June 18. Temperature  $96^{\circ}$ ; bradycardia; few râles; bronchial breathing and pectoriloquy about the same.

July 1. Chest signs about the same; temperature remains low; says he feels well.

Later, the lung showing no signs of resolution, despite various forms of treatment, it was determined to produce an abscess in the subcutaneous tissues to test the value of this procedure. I explained to the patient that this form of treatment was experimental and would probably be useless and certainly

painful. He was willing, however, to have it undertaken.

July 15, 2 P.M. Injected turpentine, one-half drachm, into subcutaneous tissue of right side of chest (anterior axillary line about the eighth rib). During the rest of the day he complained of severe pain at the seat of injection; slept but a short time during night. Temperature 102°.

July 16. Area of injection red and swollen; the left base remains about the same.

July 17. Seat of injection very red and angry looking; extremely tender over consolidated lung; fine râles on inspiration.

July 18. Beginning softening is apparent.

July 21. Abscess formed; evacuated about eight fluidounces of creamy pus. No bacteria. Lung clearing rapidly.

July 23. Abscess doing well; only very slight harsh breathing over left base.

August 4. Has gained in weight; chest perfectly clear.

The condition of the blood is shown in the following figures:

	Red corpuscles	White corpuscles.
July 15.....	4,201,000	31,563
July 16.....	4,665,000	15,625
July 17.....	4,690,000	.....
July 18.....	4,245,000	7,549
July 19.....	4,735,000	10,770
July 20.....	4,600,000	7,688
July 21.....	4,760,000	15,137
July 22.....	4,900,000	17,188
July 23.....	4,290,000	17,550
July 25.....	4,910,000	13,281
July 27.....	4,265,000	13,010
July 29.....	3,810,000	14,985

DIFFERENTIAL COUNTS OF LEUCOCYTES.

	Polymorphous.	Mononuclear and transitional.	Lymphocytes.	Eosinophiles.
	Per cent.	Per cent.	Per cent.	Per cent.
1. Before injection of turpentine, June 20.....	30	5.2	45.2	19.6
2. After injection, July 17.....	71.2	6	20	2.8
3. July 21.....	85.1	4.1	8.8	2

In this case there was not the slightest sign of resolution during a full month prior to the development of the abscess, and immediately after this the dulness diminished, moist râles became audible, and the breathing became less bronchial. In a few days the lung had cleared entirely, and the patient soon recovered completely.

*Treatment.*—In discussing the treatment of delayed resolution it is well to recognize that several causes contribute. These I have referred to above, but may again enumerate as excessive exudate, poor aeration of certain

areas, feeble circulation, and to these may be added general enfeeblement of vitality.

Various remedies have been suggested and different authors have regarded this or that drug as most efficacious. For my own part I am convinced that no form of medicinal treatment is particularly useful. I have employed tonics, stimulants, arsenic and iodide of potassium and ammonium repeatedly in the above reported cases, or in others not here recorded, without observing the slightest effect. Stimulants seem to me most rational, but I cannot say that they have ever in my experience done good by themselves.

Counter-irritation has, however, been of apparent benefit in every case in which I have made trial of it, and generally in proportion to its severity. Strong mustard poultices have sometimes been useful, but blisters were always more efficacious. I have never used the actual cautery, though I should be tempted to employ it in some cases. The action of counter-irritants might be explained in two ways: they certainly lead to increased respiratory movements for a time, and if repeated may effect a continuous beneficial effect of this kind; in the second place it is not impossible that they affect the circulation in the lungs. Caton, in a discussion some years ago before the Pathological Association at Oxford, claimed to have demonstrated that counter-irritation of the skin of the chest affects the pulmonary arterioles profoundly. This claim of course requires confirmation, but there is abundant clinical evidence of a reliable kind to show that external counter-irritation influences deep-seated structures or organs. Most probably such influence is exerted by reflex action through the nervous system.

Next to counter-irritation I should rank systematic breathing exercises, either in the form of deep inspirations and expirations, or of exercises with bottles after the method suggested by James for the treatment after evacuation of cases of empyema. Adequate breathing would perhaps properly rank as the most important requisite for speedy resolution, but in cases of marked consolidation has disadvantages, such as the tendency to exhaust the patient, and the lack of expansion of the affected side rendering the breathing useless. In cases, however, of moderate consolidation or persistent bronchovesicular breathing after pneumonia, I should rely upon breathing exercises rather than counter-irritation. In one case under my care, in a young man of about nineteen or

twenty. recovery from the active manifestations of the disease occurred normally, but for some time there was persistent semi-bronchial breathing with some dulness. He was directed to exercise his respiratory muscles twice daily, and soon began to improve. His chest expansion increased greatly, but he did not recover completely for a year. Pleural thickening may have had some part in the behavior of this case, but I could never assure myself of its existence.

In one of the cases reported I employed a rather unusual form of treatment, first suggested by Fochier (*Lyon Médical*, Aug. 23, 1891). This observer, noting that the occurrence of local suppuration in puerperal fever is often followed by improvement, suggested that artificially induced suppuration might benefit cases of puerperal sepsis. He practised injections of turpentine (about one centigramme per dose), giving three or four injections in different places. Following a suggestion of Fochier that the same form of treatment might be of use in non-pyemic diseases like pneumonia, Lepine (*La Semaine Médicale*, Feb. 27, 1892) practised it in a case of pneumonia on the twelfth day when the patient was in a desperate condition. Recovery ensued and was seemingly largely the result of the treatment. Subsequently Dieulafoy, L. Bard, Gingeot and Raoul reported successful cases, while Rendu referred, in discussion of one of the papers, to three cases that terminated unsatisfactorily. Two of these, however, were moribund when the treatment was instituted, and the third was a broncho-pneumonia and not croupous.

I have not myself employed this treatment in the class of cases in which it was recommended—that is, in pneumonias of severe character during the latter period of the process (gray hepatization)—and cannot speak of its usefulness in such cases. The instance above reported was one in which there was no immediate danger to life and no existing toxemia. Fochier advanced the theory that the artificial abscesses operate by “fixing” the toxic substances (*abscess of fixation*), but Chantemesse and others believe the beneficial effect to be somehow connected with an increase of phagocytic activity on the part of the leucocytes of the blood. Without entering into this matter I may call attention to the remarkable change in my case in the differential counts of the leucocytes before and after the injection of turpentine. The number of eosinophilous cells and of polymorphous forms was of particular interest.

The rapid increase of the latter may furnish some ground for the assumption that an increased phagocytic activity is induced, but my own view would take a different form. I am convinced that the phenomena of leucocytosis are largely the result of altered distribution of leucocytes and not of increased production. It has been demonstrated that in the process of hypoleucocytosis the white corpuscles became arrested in the capillaries of the lungs, liver, and other structures. Reversely it is likely that leucocytosis is partly at least the result of a liberation of leucocytes from various parts of the body. In such a case as I have reported it is not improbable that large numbers of polymorphous leucocytes remained within the pulmonary circulation until a more powerful chemotactic influence caused their liberation. It may be that the treatment is beneficial in this manner.

Briefly, my conclusions regarding the treatment of cases of pneumonia with a tendency to delay of resolution are:

1. In cases of slight tendency to delay of resolution manifested by moderate dulness and persistent broncho-vesicular breathing, systematic breathing exercises are of the greatest importance.
2. When considerable dulness persists, active counter-irritation should be practised and tonics and stimulants administered.
3. The production of aseptic abscesses may be useful. The cases in which this has been practised are too few to warrant absolute conclusions, and the treatment is too painful for general application.

#### THE CLIMATE OF ATLANTIC CITY AND ITS USEFULNESS IN DISEASE.

---

BY WILLIAM EDGAR DARNALL, A.B., M.D.,  
Atlantic City, N. J.

---

Forty years ago, when the beautiful island on which Atlantic City is built was an arid waste of sand, Philadelphia physicians recognized the wonderful health-giving properties of the climate it possesses. At first an occasional patient courageously ventured to the place; later, as hotels went up, they came in greater numbers; at the present day the wide-spread fame of this resort draws health seekers from all parts of the world. Abundant evidence from most credible sources now exists as to its usefulness in many forms of disease. It will be my purpose in this paper to describe some of the local condi-

tions and causes that contribute to this remarkable climate.

From meteorological tables, geographical and other data, a general opinion can be formed as to the nature of the climate of a section and whether it is favorable or unfavorable to health. It will generally be found, however, that there are strictly local conditions which should enter into consideration in determining whether a given locality is or is not the best place to send a case.

"Climate is so dependent upon purely local conditions, pertaining often to only a limited area of territory, that it is impossible for any work based solely upon official data taken at fixed points to convey anything more than a generalization. These conditions can only be ascertained by a careful study of the localities claiming the patronage of the health seeker. The physician who prescribes climatic change for his patient on generalizations will benefit just about as large a proportion of them as if he filled his prescriptions for all his patients from the same bottle. The ideal health resort must have natural conditions on which to build."\*

Geographically Atlantic City is situated on an island just off the coast of New Jersey, lying in latitude  $39^{\circ} 22'$ . This island, about three-quarters of a mile in width, and ten miles in length, is completely surrounded by salt water—a point to be borne in mind. From its magnificent stretch of ocean-swept beach, an arm of water known as "The Thoroughfare" is sent around it, dividing it from the mainland. Beyond this, extending shoreward, there is a five-mile expanse of salt meadow land.

The coast of New Jersey has a general direction from southwest to northeast, but the beach front of the island trends more to the west, thus causing it to face almost to the south. It is possible that this may be one of the factors accounting for some of the characteristics of its climate which are not possessed even by other Jersey resorts.

The soil is porous and sandy. Water therefore soon soaks through it, leaving no standing pools. Even the natural atmospheric moisture seems to be absorbed by the dry sand. The growth on such a soil is necessarily scant, preventing the possibility of disease which lurks in decayed vegetation.

It seems to be a common impression that the air at the seacoast, especially during the

winter months, must necessarily be heavy and damp. This is not so by any means. One of the most distinctive features of the climate of Atlantic City is the dryness and bracing quality of the atmosphere. There are of course occasional mists and foggy days; but by far the greater part of the time the air is dry, producing a feeling of buoyancy, as if it were wafted from mountain heights. Taking even all the misty days we have into consideration, reference to the accompanying charts will show a mean humidity extending over three years of but eighty-one per cent., while in past years it has frequently fallen below this figure.

\* This paragraph by Dr. A. F. McKay (*Medical Record*, Oct. 31, 1897) is so much to the point that I have quoted it bodily.

The dryness of the climate is, however, best shown by an examination of the rain-

fall. This will average about two and a half inches per month, or thirty inches annually. These figures are in striking contrast to those of other points along the coast. At none of them does the rainfall approach so low a point, and at many it will be seen that the annual precipitation is from fifty to sixty inches.

The question of temperature is always an important one in the study of any climate. It has gotten to be a saying among weather observers that Atlantic City breaks all rules of meteorological calculation in this regard. Severe extremes of temperature are unknown here. Even in the coldest winter weather the middle of the day is usually pleasant, the temperature at noon rarely being below 40°. As this is the most convenient time for invalids to be out, it is fortunate that it is rarely cold enough to be disagreeable to them.

On the coldest day of last winter (January 27, 1897) Atlantic City showed the highest temperature of any Eastern city, and the same average temperature for the day as New Orleans. On the other hand, during the most intense heat of July and August the thermometer seldom registered above 85°, while the average temperature at this time of the year is 71.5°.

The tables show a mean maximum temperature for three years of 57.7°, a mean minimum of only 45.5°, or an average annual temperature of 51.6°. A daily comparison will show that it is six to ten degrees warmer here in winter than in Philadelphia, and that much cooler in summer.

There are several factors to be mentioned in accounting for this remarkable record, most important of which are: the winds; the geographical position of Atlantic City, which has been described; and the Gulf Stream. During the winter months the prevailing direction of the winds is from the west and northwest. These winds come to us across sixty miles of the sandy soil of New Jersey. They are not only warmed by the radiation of heat from it, but the sand absorbs their moisture and dries them. If the winds, on the other hand, are from the south, southeast, or east, they become heated as they pass over some three hundred miles of Gulf Stream. This leaves the northeasters as the only disagreeable winds we have. Blowing down between the Gulf Stream and the coast they have no modifying influence. These, however, are of rare occurrence, and do not last longer than a day or two at a time.

NUMBER OF CLEAR, PARTLY CLOUDY, AND CLOUDY DAYS.

The nearness of such a large body of ocean water is itself an important agent in the modification of the climate. Sea water possesses a fairly constant temperature, which does not fluctuate much from winter to summer.

During the rigors of winter, when the earth and air are colder than the water, which remains constant, this fact causes the water to serve as a blanket by which the heat that would be lost from the soil by radiation is retained. Temperature is thus elevated in winter. In summer, however, the opposite effect is produced, for the atmosphere is now warmer than the water, and when everything is roasting inland the temperature is made refreshingly cool here by reason of the evaporation from the surface of so large a body of water, and the breezes wafted from it. In this way the climate is made more equable, and less subject to extreme or sudden changes of temperature either in winter or summer.

In the consideration of a place to which patients may be referred for their health, it is highly necessary that a locality be chosen which has a majority of its days bright and sunny. Dark days depress the invalid and deprive him of the sun, besides shutting him in the house, so that he also loses the benefit derived from outdoor exercise. A casual reference to the statistics disproves the com-

mon impression that life by the sea must be bleak and dreary. It is safe to say that there are at least 265 days in the year on which an invalid could be out enjoying the delights of the famous Board-walk. This leaves but 27.5 per cent. of the days—a little more than one-fourth—on which the sun hides his face entirely. Quite a percentage of these occur in March, the disagreeable month everywhere, and such weather is usually of very short duration. Most of the time the weather is bright and sunny, the air bracing and exhilarating, and the winds tempered with a softness that is surprising; while during the autumn months no wealth of words can paint the glory of the sea and climate.

Undoubtedly the most important modifier of the climate of all the Atlantic States is the wonderful influence of the Gulf Stream, which bears a peculiar relation to the coast opposite Atlantic City. It has been determined by the United States Geodetic Survey that there is a mutual relation between the moisture, temperature and barometric pressure on land and the varying velocities and different positions of the currents of the Gulf Stream. The surface velocity, according to Pillsbury, is sensibly affected by barometric differences, forming low and high areas of pressure. These currents have also daily, monthly and yearly variations in position, and each motion is no doubt governed by laws that are as yet but dimly understood. The Gulf Stream follows the declination of the moon like a needle does a magnet. Its axis moves from west to east as the moon proceeds from high declination to low, and crosses the equator. Its volume expands and contracts. Even its temperature, which is about 80°, presents variations within narrow limits.

The conclusions adopted by Professor Bache from the observations taken under his direction were as follows: "That between Cape Florida and New York the Gulf Stream is divided into several bands of higher and lower temperature, of which the axis (of the stream) is the warmest, the temperature falling rapidly inshore and more slowly outside. This is not only the case at the surface, but with modifications easily understood at considerable depths. That between the coast and the stream there is a fall in temperature so abrupt that it has been aptly called the *cold wall*. The cold wall extends with varying dimensions and changes of its peculiar features along the coast from Cape Florida, northward as far as examined. Inside this wall of colder temperature there is another

increase, while outside the warmest band, which is next the cold wall, there is another warm and one other cold band."

The innermost of these warm bands approaches as near as sixty-five miles from the coast, opposite Atlantic City. Not only its proximity to us here must be noticed, but also its course. At this point it takes a bend running a little more than a half degree of latitude to the northeast, then bending due east in latitude 40°. A certain outlying portion of Gulf Stream water, therefore, setting in the direction of this current will, when it makes this sudden turn, continue the original direction of the current, being deflected as a tangent from the curve of the stream. The beach of Atlantic City with its southern exposure is situated just where it would receive with open embrace whatever modifying influences might be derived from such a current setting in this direction. What leads me to believe this fact has some bearing on the question is that no other seaside resort even along the Jersey coast possesses exactly the climate we have here.

It may be of some interest to digress here a little in order to describe briefly the two generally accepted scientific theories of the causes of the formation of this remarkable body of water known as the Gulf Stream. These are the (a) Wind Theory and the (b) Density Theory.

(a) The *Wind Theory*, of which Pillsbury is an advocate, supposes that any permanent wind blowing constantly in the same direction across a body of water will cause such friction between the surface particles and the lower strata of the air that these particles will tend to move with the wind; also the wind caught behind the crests of waves would push these along. The friction thus produced among the surface particles of water is transmitted from layer to layer, with continually diminishing force as the depth increases. It was calculated by Agassiz that 100,000 years was ample time to allow friction of this sort to be communicated from the surface to the bottom—a depth, say, of 2000 fathoms. It is held therefore that the trade winds blowing in the same direction for ages, over the Atlantic Ocean, have by this friction process, slow in itself yet attaining a mighty momentum as the centuries have rolled on, been able to move this vast body of water along in a constant stream.

(b) The advocates of the *Density Theory* hold that ocean currents owe their origin to the difference between the specific gravity of

sea water at one place and sea water at another place; whether this be due to difference of saltness, temperature or what-not, it disturbs equilibrium so that currents result.

The effect of heat, as at the equator, causes a lesser density of the surface water, while the effect of the cold of the polar regions causes a greater density. This latter, being heavier sinks as it is cooled by reason of its greater specific gravity and diminished bulk, and sinking, causes a flow of water to be drawn into its basin from the surrounding surface area of water. Such a supply must come from a yet greater distance; and so this cooling causes a set of water in the direction of the poles, when a corresponding deep-down current of cold water sets toward the equator to be again heated.

Also precipitation over the central portion of the water hemisphere of the earth is greatly in excess of evaporation. Northwards evaporation is in excess of precipitation. The water thus drawn from polar seas by evaporation is quickly hurried down to the areas of low barometric pressure, where precipitation follows. But its loss from the polar regions makes the basin referred to above still larger, and so adds an additional impetus to the set of the water northward. The disturbance of equilibrium thus produced between equatorial and polar water, by cooling and evaporation, causes a steady current to flow from gulf to poles, and a return undercurrent from poles to the equator.

These are in brief the two most prominent among the many theories that have been advanced as to the formation of the Gulf Stream. It must be true that warm water comes from the equator and cold from the polar regions, and whatever be the mode of transfer the modification of climate is due to its presence rather than to the method of its delivery.

But to return to Atlantic City. After having studied the meteorological conditions and geographical environments that conduce to its unique climate, the practical question naturally arises, What is it good for? What classes of disease will receive benefit by a sojourn in such a climate? Climatology is a subject beset with many and peculiar difficulties. While a great and growing department of therapy, it is as yet but dimly understood by the bulk of the profession. Formerly climatic change was only thought of as a remedial agent in respiratory diseases. Now every chronic deviation from health is studied with reference to change. Such change,

however, must not be recommended in a haphazard way. There must be some rational basis underlying it if any good is to be derived therefrom.

The climate of Atlantic City is a dry one, tonic and alterative in its qualities. Its air is both a stimulant and a sedative. Actual experience drawn from many sources has demonstrated that those suffering from almost all functional disturbances, nervous prostration, overwork of both mind and body, depression from any cause, indigestion, insomnia, or any torpid state of the system, as well as strumous conditions and diatheses, are much benefited by the bracing qualities of the air. Residence here has proven of inestimable value to that elderly class of cases whose health and strength seem to have forsaken them, making them chronic invalids. Long-lasting and obstinate diseases of women rebellious to treatment at home oftentimes show marked improvement or disappear entirely under the alterative influence of the air here.

There is a class of cases in the practise of nearly every physician whose management becomes very trying to his skill. These are the convalescents from severe and exhausting diseases or operations who seem to reach a standstill. They remain without improvement of vitality or appetite till the patience of the family becomes exhausted, while the physician pursues resource clear to the end of his string without avail. Such cases usually have an appetite before they have been here twenty-four hours; they seem to improve almost as they cross the meadows. As soon as they come under the influence of the stimulating air oxidation is increased. Its soporific effect is at the same time a sedative to a disordered nervous system. Its purity and freedom from unsanitary conditions and miasmatic influences allows more rapid elimination of deleterious matter from the system.

On the other hand, the softness of the air and its balmy warmth soothes the stiffened joints of the gouty and rheumatic; relieves the distress of emphysema and asthma, especially those cases coming from inland or from high altitudes. There are some asthmatics, however, whose difficulties are aggravated by coming here. These should seek the warmer, more sedative climate of the far South. The cases that do not do well at the seashore will oftentimes be relieved by the mountains, and *vice versa*.

Whether due to the antiseptic and alterative qualities of the atmosphere, or to the absence

of the pollen of vegetation, sufferers from hay-fever enjoy comparative immunity from their malady. Atlantic City has been referred to as a "hay-fever paradise!" Most noteworthy perhaps and most striking is the number of people living here who have been cured of chronic bronchial and catarrhal affections. This is no doubt brought about by the alterative influence of iodine, bromine, chlorine, oxygen, and the ammonia salts, with which every inspiration they breathe is laden. At the same time it must be remembered that the air is pure and free from the dust of a city, factory smoke, exhalations from slum districts, and other impurities that serve to keep up an irritation once started in the respiratory tract.

Skin diseases are not common here. They are often mitigated or disappear entirely, for the atmosphere, while dry, is not irritating to the skin like that of high climates.

The profession formerly held that high altitudes were better adapted to beginning cases of phthisis. The trend of opinion, however, now seems to be that neither wind, humidity nor altitude in themselves and apart from other factors play so important a part as do the purity of the air, its percentage of free ozone, and the absence of unsanitary conditions. Cold, humid winds chill the surface of the skin by conducting away its heat, and drive the blood inward. It is easy to see that this does an already inflamed lung no good. Such weather should always be avoided therefore by a consumptive. Raw or penetrating days will occur at times in every climate. Atlantic City, however, has a very small percentage of such days, and they soon give way to sunny weather again.

Much may be said in favor of this place as a resort for tubercular patients. Not a small advantage is its proximity to the large centers of population. Long journeys from home are always depressing to invalids. The best results may often be obtained by sending the sick one to a place near enough to his home for him to enjoy the comforts of friends, and where the change will not be too radical.

The following points have been enumerated as reasons why the well known climates of New Mexico and Southern California are model ones for phthisis, viz.: (1) A dry, aseptic atmosphere; (2) a maximum of sunshine and a minimum of cloud; (3) a slight variation of temperature between extremes of heat and cold; (4) a minimum likelihood of sudden changes of temperature; (5) a light, porous soil.

If what has been said in this climatic study has been carefully followed and the tables examined, it will be easily seen that Atlantic City meets these requirements adequately in each case, and her climate stands as the peer of any resort for phthisical patients. In the earlier stages of the disease, when it is threatening rather than in actual progress, or if the area of diseased tissue is small, not progressive, no wasting nor hectic of importance, and digestion is good, it may be recommended with confidence. This climate is especially good where tuberculosis has resulted as a part of a general breakdown from overwork, and where excavation is not rapidly extending.

Cases of fibroid phthisis, or phthisis associated with catarrhal or laryngeal trouble, much nervous irritability, emphysema, bronchitis, bronchiectasis, organic heart disease, or any brain or spinal affection, and in other conditions where high altitude is directly contraindicated, will usually receive much benefit here. Even in advanced cases with double cavities, degenerative diseases of the blood-vessels, ulceration of the intestines or albuminuria, temporary improvement may often take place. It is only temporary, however. The death warrant of such patients has already been written. Their best place is home, where their latter days may be made comfortable and their end be among friends. If they insist on climatic change the warm and sunny South is better for them and may prolong their lives a short time. The air here is too stimulating for this class of cases.

In conclusion, I wish to make acknowledgments to Prof. Willis L. Moore, chief of the United States Weather Bureau, for the tabulated statistics he has so kindly furnished me, and to the United States Geodetic Survey for the report of the investigations of the Gulf Stream.

1719 PACIFIC AVE.

*DANGER OF INJURY TO THE HEART IN  
THE TAPPING OF THE PERICARDIUM  
FOR THE RELIEF OF PERICAR-  
DIAL EFFUSION.*

BY H. A. HARE, M.D.,

Professor of Therapeutics in the Jefferson Medical College  
of Philadelphia.

---

The importance of giving relief to patients suffering from cardiac and respiratory distress as a result of an accumulation of fluid in the pericardial sac renders it advisable for us to

consider the best means to this end. Every physician of large experience finds it necessary from time to time to aspirate fluid from the pleural cavities to relieve the patient of the symptoms arising from interference with respiration, or from the peritoneal cavity to relieve distress due to distention and pressure. Very few of us, however, resort to such means of relief when we believe that a pericardial effusion of dangerous extent impairs the efficiency of the heart; first, because the diagnosis of pericardial effusion from cardiac dilatation and enlargement is difficult, and second, because the fear exists that the heart may be wounded. This fear of a cardiac wound is the cause of the timidity, for many have the idea that a cardiac wound means death and therefore hesitate lest the immediate result of the operation be fatal. My object in this paper is to point out the fact that wounds of the heart *per se* are not necessarily followed by serious results; that paracentesis pericardii should be performed oftener than it is; and that the physician in charge of cases of infectious disease, whether they be pneumonic, tubercular, or rheumatic, should remember that pericarditis with effusion often develops insidiously and is responsible for many signs of cardiac embarrassment and death which are erroneously considered to be due to heart clot or degenerative processes in the myocardium. While recognizing the great difficulties in differentiating between pericardial effusion and pericardial thickening, hypertrophy, dilatation and displacement of the heart, these will not be considered in this paper. They will be found well discussed in Dr. Frederick C. Shattuck's paper which was read before the Association of American Physicians in May, 1897. From this and many other papers it is evident that life can be saved by tapping the pericardium in a certain proportion of cases in which an effusion exists, and to those who are particularly interested in this subject we may mention three other notable papers on the methods of tapping the pericardial sac, namely, the exhaustive paper of Dr. John B. Roberts, published some years ago, and two others read this year at the meeting of the American Surgical Association by Porter of Boston and Roberts of Philadelphia (*American Journal of the Medical Sciences*, December, 1897), the latter gentleman thus making his second contribution to the subject. These papers also prove the usefulness of this mode of obtaining relief in pericardial effusions.

We pass on, then, to a consideration of the question as to the danger of heart wounds. An examination of the literature shows that injuries to the heart are by no means necessarily fatal, and that when death is produced by a wound of the heart muscle, death often does not ensue as rapidly as [if it were a wound of a large blood-vessel. An illustrative case of this character is one recorded by Cristiani in *Lo Sperimentale* for March, 1889: A man aged twenty-five was stabbed, in a brawl, in several places. One wound was in the fifth interspace on the left side, near the anterior axillary line. There was a second wound in the eighth interspace on the same side, extending from the posterior border of the axilla toward the shoulder blade. There was also a stab of the left hip and several stabs on the right arm. After the second wound was received—the one near the præcordia—the man fell, but retained consciousness. After being taken home he was seen by a physician, who found him still conscious, with respirations at fifty a minute and pressing dyspnea. This state lasted for eight or ten days. The wound over the heart healed in seven days, and that in the eighth interspace in eight days. On the eighteenth day the patient got up, though still weak, and on the thirty-seventh day, while yet feeling ill, he walked to Pisa and back—a distance of six miles and a quarter. This was done in the morning; in the afternoon of the same day he walked nearly two miles, climbed a tree after a bird's nest, and fell to the ground, dying ten minutes later.

At the autopsy it was found that the wound in the fifth interspace had penetrated the pericardium and deeply wounded the wall of the left ventricle at a distance of three and a half centimeters from the apex, but had not actually entered the ventricle. The mouth of this wound was filled with a soft clot, which was removed, and a mass of organized blood-clot was found below it. This mass had ruptured by reason of the increased strain, so that there was an opening into the ventricle through which the fatal hemorrhage took place into the pericardium.

In the same article is a report by Messeri, of Florence, relating the case of a man thirty years old, who was stabbed in the fourth interspace a half inch to the left of the sternum. When admitted to the hospital he was apparently dying, but he soon recovered, and his wound healed rapidly. Twenty-one days later he asked to be discharged, and when this was refused fell into a rage and

dropped dead almost at once, with cyanosis and dyspnea as prominent symptoms. The thorax contained much blood, and an open wound was found in the right ventricle near the sulcus, and also a wound of the septum. Messeri also refers to statistics collected by Zanetti, who finds that in one hundred and fifty-nine cases of wound of the heart, in only ten was the septum injured; and that in seven of these death occurred at once, in one it took place in an hour and a quarter, in another in two hours, while the other patient lived twenty days.

Having recently had occasion to look into this matter myself, I have found in medical literature a number of cases recorded where similar survival after severe injury occurred. Thus, Fischer has collected four hundred and fifty-two cases of injury to the heart and pericardium, in no less than seventy-two of which the patients recovered, while in two hundred and seventy-six death took place at periods varying from one hour to nine months. Death was immediate in one hundred and four cases. Of the seventy-two recoveries, examinations, made long after, in thirty-six of the cases proved the diagnosis to be absolutely correct. Of these seventy-two cases, ten were punctured wounds, forty-three incised, twelve gunshot, and seven lacerated; fifty were wounds of the heart, and twenty-two of the pericardium.

Purple also records forty-two cases of wounds of the heart in which death did not come on immediately. Randall records a case of a colored boy who lived sixty-seven days with a number of shot in the heart muscle, and Ferrus a case in which the patient lived twenty-one days with the heart transfixed with a skewer.

Ollivier and Lawson have collected twenty-nine instances of penetrating heart wounds, of which only two proved fatal within forty-eight hours; the rest of the subjects died in from four to twenty-eight days after receiving the injury. The Duc de Berri lived eight hours after a wound of the left ventricle; and Watson saw a case in which a man ran eighteen yards after receiving such a wound. Those who are interested as to further discussion of this subject I may refer to the paper of Mesbrenier in the *Annals d'Hygiene*, 1879, vol. i, p. 257.

Still more recently we find Morgan in the *Edinburgh Medical Journal* for December, 1897, recording the case of a boy aged five years who fell upon a needle so placed in his shirt that the fall forced the steel into the

heart so that it moved to and fro synchronously with the heart. The child was chloroformed and the needle withdrawn, recovery taking place.

Another case is that reported by Prior in *The Lancet* of October 9, 1897, of a man aged forty-three years, an epileptic in an asylum. The attendant in charge in the sick-room observed the patient doing something unusual, and on removing the bedclothes was astonished to find an iron pin projecting from the chest in the region of the heart. The exact situation was one and three-fourths inches below and one inch internal to the left nipple. The pin was directed slightly upwards and inwards. It moved vigorously with every beat of the heart and traveled about an inch upwards and downwards every time. On examination the pin was felt to be firmly embedded in the wall of the heart, which was felt tugging at the inner end of the pin. Removal of this peculiar foreign body was not undertaken without some misgivings as to the result. The pin was rotated and gently withdrawn; the part within the chest measured three inches, making a total length of four inches of three-tenths inch iron wire. The patient was collapsed; he had a small, feeble pulse, 64 per minute; respiration was shallow, 24 per minute; and the skin was cold. There was practically no hemorrhage from the wound. No external hemorrhage appeared subsequently to this, and there were no signs of effusion of blood or serum into the pericardium. The patient kept his eyes closed. He did not resist an examination of the pupils, which were dilated and reacted but slightly to light. When spoken to he would not answer. Prior thought he was conscious of all that was said, and subsequent events made this almost certain. The wound was dressed antiseptically, and there was no visible suppuration at any time. On the day following the infliction of the wound there was some subcutaneous emphysema round the wound. The physical signs of pneumothorax appeared, but this and the emphysema disappeared again in twenty-four hours.

The following case of heart wound has been reported by Rehn: A young man was brought to hospital, having received an injury from a knife in the left side of the chest. There was much dyspnea and hemorrhage. As the pericardium became dilated the patient's state became worse and worse. The wound in the fourth intercostal space was then opened up, and after resection of the

fifth rib the pericardium was incised. A wound one and a half centimeters in length was then found in the right ventricle. This Dr. Rehn closed by three sutures and packed the pericardial cavity with iodoform gauze. After the operation the pulse and respiration immediately improved, and although the patient's convalescence was retarded by suppurative pleuritis he made in the end a complete recovery.

Finally, the following personal experience is of interest, although the results from the standpoint of relief of cardiac difficulty were not permanent. A boy nineteen years of age, during the course of a severe attack of articular rheumatism, developed great pain over the præcordium, and in the course of forty-eight hours marked interference with normal heart action, dyspnea, cyanosis, and great præcordial discomfort. He had had since early childhood severe attacks of rheumatism at varying intervals, and as a result of these attacks had developed a marked mitral regurgitant murmur. The symptoms of cardiac oppression increased in intensity, but a physical examination of the chest failed to reveal any trouble with the lungs, although there was a great increase in the area of præcordial dullness. Under these circumstances it was evident that the extension of cardiac dullness in every direction could only be due to two causes—either a pericardial effusion or marked cardiac dilatation. The symptoms increased in severity, and became so aggravated that it was evident the patient would die in a very short time if some active interference was not resorted to. Under these circumstances I asked my colleague, Dr. J. C. Wilson, to see the case with me in consultation, and we both decided that we were justified in resorting to paracentesis pericardii, with the hope that by withdrawing pericardial fluid we might relieve the labored action of the heart. After careful percussion and deliberate outlining of the areas of cardiac dullness, I inserted a trocar and cannula attached to an aspirating flask into the fifth interspace immediately to the left edge of the sternum. The impulse of the heart was immediately transmitted along the cannula as soon as it entered the chest, and on turning the stop-cock the aspirator withdrew several drachms of blood. This sign, combined with the active movements of the cannula, which was evidently engaged in the heart muscle, apparently indicated that the heart had been punctured, and fearing that serious results might follow the instrument was at

once withdrawn. Instead of the patient becoming worse, however, he immediately improved and for a number of hours seemed much relieved, perhaps because by the withdrawal of the blood we had relieved auricular or ventricular distention and the wound closing had prevented hemorrhage into the pericardial sac. On the following day, the symptoms having returned in all their severity, it was determined to once more attempt to withdraw fluid from the pericardial sac, in which it seemed certain that fluid existed. Another attempt, however, was equally barren of results so far as fluid was concerned, the cardiac cavity being tapped a second time and pure blood withdrawn as before. This second wound of the heart also resulted in temporary amelioration of the case, the patient dying about thirty-six hours afterwards from a gradually increasing cardiac failure.

By far the most recent and important study of this question, however, has been made by Bode (*Beiträge zur Klinische Chirurgie*, Band xix, Heft 1). This research showed that large wounds of the ventricle which impaired its action soon resulted in death, for this reason, or because of hemorrhage into the pericardium; whereas in the case of small wounds of the ventricle the hemorrhage gradually ceased and finally stopped spontaneously, the time of repair or arrest of the hemorrhage being quite short. He also found that small wounds of the left ventricle bled much less freely than similar wounds in the other parts of the heart, evidently because of the greater muscular thickness of its walls which by the arrangement of its fibers mechanically prevents hemorrhage and aids clotting. That this protective process takes place is proved by the cases of temporary recovery followed by sudden death, when severe strain has displaced the plugging clot, which have been cited in this paper.

In a research carried out by the writer, the results of which were published in the *Medical and Surgical Reporter* in 1889, these last named facts were frequently noted, and a recent study of the hearts of the dogs used at that time shows very well that this plugging of a cardiac wound by a clot often occurs and thereby saves life. It also showed that an injury to the heart muscle, unless of great extent, did not of itself necessarily or even generally cause death, and that in a number of cases where death did result from a stab wound of the heart this result did not arise from the cardiac injury directly, but

either from the loss of blood through the wound in the pericardium and heart wall or much more commonly from the pressure exercised upon the surface of the heart by the accumulation of fluid in the pericardial sac. The conclusions to be reached, therefore, seem to be as follows so far as actual cardiac wounds are concerned: There are therefore several ways in which death may occur in cases of heart wounds: (a) By hemorrhage which results in loss of blood or great pericardial pressure from the cardiac cavities; (b) by hemorrhage from the heart muscle itself, which is unusually slight; (c) by a wound of the coronary artery; (d) by injury to the center which Kronecker and Schmey have localized in the dog's heart—a spot above the lower limit of the upper third of the ventricular septum, which, when it is injured, brings the heart to a standstill. This is the so-called coordinating center.

We may conclude therefore that the lethal result of a heart wound depends largely upon the rapidity with which a hemostatic clot is formed in the opening, and that injury of the heart muscle in itself is rarely the cause of death. Only when the coordinating centers are injured or there is profuse hemorrhage into the pericardial sac, which produces cardiac failure by pressure, does death occur, unless the wound is so large as to permit the blood to escape externally or into the thoracic cavity. The opening made by a small aspirating cannula is never large enough to produce hemorrhage from the ventricle.

Heart wounds heal by the formation of hemorrhagic exudate, which plugs the leading opening and permits repair.

#### THE POST-OPERATIVE TREATMENT OF SURGICAL CASES.

---

BY THOS. LEIDY RHODES, M.D.,  
Assistant in the Surgical Clinic, Jefferson Medical College  
Hospital.

(Continued from page 22.)

When an operation is performed, as it frequently is, on patients who are suffering from an acute or chronic urethritis, the prolonged exposure of the patient on the table and the administration of required alcoholic stimulants will often light up an acute inflammatory process, which will result in complete obstruction to the urinary outflow—a condition known as retention from inflammatory stricture. Any part of the urethral tract may become sufficiently involved in this

process to produce this complication, but the existence of inflammation in the deep urethra, a severe posterior urethritis, is the most fruitful cause of the trouble. The area of inflammation is not, however, always limited to the urethra itself, and combined with a specific urethritis there may be an associated acute or recurring prostatitis, from extension of the urethral infection to the prostate gland. In either case the retention is primarily purely mechanical; the inflammatory process becomes so marked, the urethral mucous membrane, or the prostate, or both, become so inflamed and swollen as to impinge upon the lumen of the urethra, and in a short time the vesical outlet is completely blocked. It must not be overlooked, however, that the element of spasm, from the involvement of the peripheral ends of the sensory nerves of the urethra in the inflammatory process, and the subsequent reflex disturbance, enters largely as a causal factor in the inhibition of the vesical function. The diagnosis of the exact condition causing the retention from that of a simple spasmodic trouble will be readily determined by inquiring into the recent history of the patient, the existence of a free discharge, the associated febrile disturbance, and the pain along the course of the urethra. Digital exploration of the rectum will determine the existence or non-existence of prostatic tenderness and swelling.

The treatment will consist of such means as are mild and gentle in character. If the character of the operation permit, the patient is placed in a hot general bath, or a hot sitz bath, for fifteen minutes, and is given a hot lemonade. In lieu of the general bath, or sitz bath, if these be not permissible, the patient may be wrapped in a blanket wrung out in hot water, or the local use of hot fomentations to the perineum and hypogastrium may be substituted. At the same time it is well to administer an initial dose of morphine and atropine by subcutaneous injection. This failing, the rectum is irrigated by means of a fountain syringe and rectal irrigating pipe having an opening for the return flow, with several quarts of hot saline solution, the nozzle of the tube being directed anteriorly against the prostate to get the full local effect on the congested gland and neighboring area. At the same time two or three leeches should be placed on the perineum if the prostate gland is much inflamed. These means still failing to relieve the retention after the lapse of two or three hours, a small soft-

rubber catheter is passed after a preliminary mild antiseptic irrigation of the anterior urethra. A No. 15 F Jacques' catheter having previously been sterilized in the Guyon box, or in emergency by boiling, is attached to an irrigating bottle containing half a liter of potassium permanganate solution 1:4000. The bottle is raised one meter above the patient, and while the solution continues to flow through the tube and catheter, the latter is introduced into the urethra until the eye of the instrument is opposite the bulb. The irrigation is here completed and washes out all the purulent contents from the anterior urethra. Occasionally, while this is being done, the parts become so relaxed that the patient will void his urine while the irrigation is in progress; but if not, the irrigating bottle and tube are disconnected and the catheter is passed into the bladder—usually without any great difficulty. Owing to the hypersensitiveness of the urethra from the inflammation that is present, the procedure may at times be accompanied by such unbearable pain as to require the induction of light anesthesia with ether or bromide of ethyl before the catheter is introduced. This is, however, necessary only in rare instances. The catheterization is repeated at intervals of four hours, providing the bladder does not empty itself spontaneously; but before catheterizing, the milder means mentioned should be tried each time faithfully, to see whether they will not suffice. At intervals suppositories of belladonna and opium are administered for their antiphlogistic and relaxing effects, and if the fever runs high and local tenderness is especially severe, rectal injections of ice-water will give relief. The bowels are opened freely by salines, the urine is rendered bland by co-paiba and sandalwood oil, and the kidneys flushed with diluent drinks; a restricted diet, principally of milk, is strenuously adhered to, and the recumbent posture is maintained until the inflammation is controlled and there is no longer danger of retention.

When retention comes on as a consequence of organic stricture, a different phase of the problem presents itself. The patient, usually an adult male, having for some time previous to the operation experienced some difficulty in urination, marked by frequency in micturition, dribbling, the voiding of a small stream, and an associated gleet discharge, suddenly finds himself, at the completion of an operation, unable to pass his water. Here, too, as in the case of retention due to acute inflammatory engorgement of the urethral

tract, the exposure and environments of the operation, the chilling effects of the anesthetic, and possibly the necessary administration of alcoholic stimulants, have much to do with precipitating the sudden obstruction to the outflow of urine. Organic stricture, being the cicatricial result of a chronic interstitial inflammation, is always accompanied by a certain degree of this inflammation, more especially in the mucous membrane immediately back of the stricture, where the pouching of the urethra as the stricture grows smaller, and the erosion of the mucous membrane from the decomposition of a few drops of retained urine, favor the rekindling of an active inflammatory process in the stricture band itself. Accordingly, when such pernicious influences are brought to bear upon this condition, an inflammation not only of the urethra posterior to the stricture and the tissues tributary to it may result, but also an inflammatory infiltration of the fibrous ring itself, with a tendency to obliteration of the entire lumen of the canal.

The strictures thus causing retention in the great majority of cases are situated in the bulbo-membranous portion of the urethra, are generally multiple, particularly if the primary cause be gonorrheal infection, and their elasticity or density is commensurate with the duration and degree of the pathological process. This can, to a certain extent, be determined from the history previously elicited from the patient.

The treatment of the condition will begin immediately the retention is discovered. If there are no contraindications, the patient is placed in a hot general bath or a sitz bath; or, towels are wrung out in hot water and wrapped about his thighs and loins, the bed being properly protected. At the same time he is given a full dose of morphine sulphate (one-third grain) hypodermically or by suppository, or the same amount of the acetate by mouth. If the bladder is unable to expel its contents immediately after the bath or hot applications, instrumentation will be indicated. These strictures are necessarily impenetrable to soft catheters, sounds, and cutting instruments alike, and the instrument of choice for the relief of the condition will be the whalebone filiform bougie. The attempt at passing a catheter or sound is absolutely contraindicated, as it will only tend to increase the difficulty in relieving the bladder by the added urethral spasm which such an unsuccessful maneuver would induce. The filiforms should be thin and strong, those

usually purchased in the shops being entirely too thick to render the best service, and it is advisable in preparing them to scrape them with some sharp instrument in order to make a slender neck with a small olive point, the best size instruments being such as will permit the passing of the smallest size Gouley catheter. A dozen filiforms are sterilized, as were the soft instruments, by trioxymethylene in the metal box, after they have received the preliminary scrubbing with soap and water, and are soaked in bichloride solution 1:1000. The region about the fossa navicularis is disinfected as before. If there is any urethral discharge, the urethra is first flushed anterior to the stricture with hot boric acid solution fifteen grains to the ounce, or potassium permanganate solution 1:5000, by means of an irrigating bag and a short urethral nozzle. With a cleansed piston syringe, a drachm of the sterile lubricant is injected into the urethra and a filiform is passed down to the stricture. If after patient and gentle effort it refuses to pass the stricture, another is passed alongside the first, is likewise rotated and pushed, and still another until the shelving band is completely occupied with filiforms, and by successive efforts one is finally pushed through the opening. All organic strictures are permeable to filiforms, and painstaking effort will surely find the minutest opening. It is impossible to state definitely just what number of filiforms will be required before this is accomplished, but the average number found necessary in the writer's hands is about eight. The moment the instrument passes the stricture, the condition is conquered, and the remaining filiforms are withdrawn.

All will now depend upon the condition of the patient, and the character of the stricture, whether the bladder shall be emptied at once or whether the filiform is to be tied *in situ* and the urine allowed to trickle slowly by the instrument. If the patient has undergone a severe operation and is very weak, or if the stricture be highly resilient, no further effort is made, capillary drainage being depended upon to relieve the retention. If, however, the patient's strength permit, and the stricture be elastic, the smallest size Gouley metal catheter, which has been sterilized by boiling, is threaded over the filiform until it meets the stricture, when the filiform is slightly withdrawn, and *both* instruments are pushed into the bladder together. The metal instrument is withdrawn, and the two larger Gouley catheters are successively

passed in a similar manner, immediately followed by a Jacques' catheter, by which the bladder is completely emptied. If for various reasons the deep stricture is not considered amenable to further dilatation at once, the rubber catheter is tied in for three days, urethral irrigation alongside the instrument from a high pressure (nine feet) being practised daily, after which the various methods for curing the stricture are made use of. If, however, moderate dilatation can be carried out at once upon the withdrawal of the soft-rubber instrument, several flexible loaded bougies, as advocated by Professor Hearn, are introduced in ascending sizes until the stricture is dilated to No. 18 of the French scale, which will prevent any further danger of retention for the time being and will pave the way for gradual dilatation with steel instruments during the course of the convalescence.

If the resiliency of the stricture prevents passing the Gouley instrument at once, or the weakness of the patient demands temporizing measures, the filiform is tied in and allowed to remain for twenty-four hours. The first drachm of urine passed in this way from the distended viscus will give untold relief to the patient, and he will rest in comparative comfort as drop after drop is drained off and the tension of the bladder is relieved. At the end of the first day it is usually possible to pass the Gouley catheter over the filiform, even though the stricture be very resilient. If the density of the band makes the passage of the metal instrument difficult or impossible, the filiform is allowed to remain in the urethra for several days longer, daily urethral irrigations and the internal administration of boric acid and salol in tenn-grain doses preventing the occurrence of any septic process; and when the progress of recovery has so far advanced that the shock and depression of the original operation will no longer be considered a menace to further interference, suitable means are instituted for the relief of the stricture itself according to the indications of the case—in general, internal urethrotomy if the fibrous stricture be anterior to the bulb, external urethrotomy (Syme's operation) if it be behind the bulb and permeable to the grooved or tunneled staff, perineal section if it be impermeable to the guide.

Occasionally retention is met with after operation in patients who suffer from stricture resulting from a former severe injury to the perineum, and it will be most difficult, and at times impossible, to pass even the

smallest filiform through the hard, nodular, cartilaginous band, which is now essentially a traumatic stricture. It devolves upon the surgeon, however, to relieve the distended viscus without delay, and the cardinal resort will be found in suprapubic aspiration. The region above the pubes is shaved and disinfected, the distended bladder is outlined by percussion and palpation with cleansed hands, a puncture is made in the skin in the median line an inch above the symphysis pubis, and a sterile, medium-size aspirating needle is plunged directly backward through this puncture into the bladder—entrance into its cavity being indicated by the lessened resistance to the instrument. The bladder is emptied as completely as possible and the needle is withdrawn quickly so as to prevent the urine from escaping into the path of the needle and causing infection, the punctured wound in the skin being sealed with sterile cotton and collodion. When an aspirating apparatus is not at hand, a small sterile trocar will answer the purpose, a large-sized instrument being avoided, as there is too much danger from leakage of urine into the prevesical fat, with the consequent formation of an abscess. In the absence of either of these appliances, perineal section will be performed, making use of the staff devised by Professor Horwitz, which instrument is brought into contact with the stricture, and with a filiform as a guide will determine the exact point for the incision; a silver or soft-rubber catheter is then passed into the bladder and tied in position for three or four days, after which bougies will be used; or if complications exist which prevent the use of the staff, and there is great urgency from the retention, Cock's operation of tapping the urethra at the apex of the prostate behind the stricture will be indicated, and a drainage tube temporarily fastened in the perineal wound, the stricture itself receiving attention in due time.

After any of these operative methods, and before they are practised if possible, the internal administration of boric acid and salol, combined with the frequent local irrigations with mild antiseptic solutions, will be most efficient means of preventing urethral fever by rendering the urine antiseptic and keeping the urinary outlet sweet and clean.

Should retention come on later in the course of recovery, or during convalescence, from the closure of a slowly contracting or recurring stricture, the condition will be met with the same means as set forth above.

Retention of urine from organic stricture in women after operation is such a rare occurrence that it does not call for a detailed line of treatment at this time. Unlike the spasmodic retention which occurs so frequently in women after operation and which is easily relieved by the sterile glass catheter when milder means fail, the cases are exceptional in which the urethral caliber is so encroached upon by fibrous contraction as to seriously interfere with the function of micturition. When the condition does occur, the insertion of a filiform, followed by dilatation with short, straight steel sounds, or if resilient, by use of the urethrotome, will not only relieve the retention, but will usually prevent further recurrence from this cause.

(To be concluded.)

#### PRIMARY TUBERCULOSIS OF THE RECTUM, WITH REPORT OF CASES.

STRAUS publishes an interesting article on this subject in *Mathews' Quarterly Medical Journal* for January, 1898. He reaches the following conclusions:

1. That primary tuberculosis of the rectum is not so infrequent as some of the leading authorities have taught.
2. That it is a surgical disease as much as is appendicitis.
3. That it is not and cannot be diagnosed by the clinical symptoms as given by the various writers on diseases of the rectum.
4. That the only scientific and correct way of making a diagnosis is by the use of the microscope.
5. That by thorough curettement or excision, or both together, with cautery, it is not only cured but remains cured much more often than is dreamed of; certainly more often than the teaching of the authorities would have us believe.
6. That some of the apparently most hopeless cases are cured by repeated operations.
7. That all suspicious cases should be submitted for microscopical examination, for the reason that it is the only scientific method of reaching a diagnosis.
8. That local treatment is not equal to curing these cases; permanent results are to be had by a radical destruction of diseased tissue or the habitat of the tubercle bacilli.
9. That these cases are and have been cured, and that sufficient time has elapsed for us to conclude that they will remain cured.
10. That early and repeated operations if need be are imperative, if these cases are to be permanently cured.

## Leading Articles.

### THE USE OF HYPODERMIC INJECTIONS OF SALT SOLUTIONS IN UREMIC ECLAMPSIA.

During the past eighteen months the THERAPEUTIC GAZETTE has contained on a number of occasions original, editorial and progress items dealing with this and kindred subjects. With practically no exceptions the reports made by English, European and American physicians in regard to the results produced by hypodermoclysis have been most favorable, particularly when we take into consideration that many of the conditions calling for this plan of treatment are exceedingly grave and followed ordinarily in the great majority of instances by death. It is not to be supposed that the hypodermic injection of salt solution in any quantity can cause kidneys hopelessly diseased to carry out their normal functions, nor that it can overcome the results of profound septic poisoning; but it is a fact that in a certain proportion of cases this method of treatment so aids the ordinary emunctories of the body, partially or temporarily disabled by disease, in carrying out their function with sufficient

completeness as to permit recovery to take place. The possibility of applying this treatment to a large variety of diseases has not failed to impress itself upon the professional mind, and we now read of cases of puerperal sepsis, uremia, septic poisoning, and even instances of infectious diseases, such as scarlet fever, in which hypodermoclysis has brought about the most happy results.

In the *Australian Medical Gazette* of September 20, 1897, Surgeon-Major Eakins records a case of uremic eclampsia in which the patient, a primipara of twenty-eight years, recovered after treatment by the hypodermic injection of salt solution, although she was unconscious five days. When first seen she was in violent convulsions. After cleansing his hands and also the vulva and vagina of the patient with ethereal antiseptic soap, he easily dilated the cervix and extracted a dead male fetus by the feet, and this was followed by a live female infant which shortly afterwards died. The thighs were now quickly cleansed with the same soap, a cannula inserted under the skin of the right thigh, and a pint of saline solution was allowed to flow in so that it was under the skin in about ten minutes. The cannula was then removed and introduced into the front of the left thigh and another pint given. Shortly after this Dr. Eakins administered one-third of a grain of pilocarpine hypodermically to aid in producing a sweat. The patient was wrapped in hot blankets and also received some digitalin and strychnine to prevent cardiac depression. A number of hours later, as no urine had been passed and catheterization proved the bladder to be empty, and the bowels had not acted, another pint of saline solution was given. Nourishment was also afforded her in the form of Mosquera beef jelly in solution. This was given by the rectum on a number of occasions. Four days after the patient was first seen she was able to take some milk and water by the mouth, but did not answer when spoken to, and passed but four ounces of urine. After this, however, she made a good recovery. Dr. Eakins believes, and we agree with him, that in the treatment of this case he took advantage of every means to save his patient: First, the administration of chloroform and her rapid delivery, thus emptying the uterus of its contents; second, allowing of free bleeding from the uterus, thus obviating blood-letting, which he believes is very useful either with or without hypodermoclysis; third, the diluting of the blood and its con-

tained poisons by the hypodermic injection of fluid on a number of occasions over and above those already mentioned; fourth, the promotion of elimination by the skin and bowels, and the use of warm water irrigation by the bowel to aid in producing a movement and to wash out poisons. Dr. Eakins concludes his article by emphasizing his firm belief that the hypodermic injection of saline fluid is much to be preferred to the intravenous method.

Another article by Dr. Bacon in the October number of *Medicine* also recommends the use of normal saline solutions in general obstetric practise, not only for the relief of toxemia producing eclampsia, but also in cases of postpartum hemorrhage or hemorrhage occurring at other times. If it seems inadvisable to use hypodermoclysis in a case of hemorrhage, the saline solution may be introduced into the body by intravenous injection, by injection into the peritoneal cavity, or, if the case is not pressing and slow absorption is desired, by high injections into the bowel, after the alimentary tract has been emptied of fecal matter by an ordinary enema.

Without doubt the best means of using saline solution in any one of these ways is by means of a hydrostatic or fountain syringe, or better still by the use of the ordinary glass irrigating apparatus commonly used for surgical practise. As the preparation of the normal salt solution requires a considerable amount of time and a careful measurement of the quantity of salt, we have recently suggested that a saturated solution containing normal saline ingredients, representing as nearly as possible the blood constituents, should be prepared, and this solution, by the proper addition of pure water which has been sterilized by boiling, can then be speedily employed.

---

#### THE USE OF PERMANGANATE OF POTASSIUM IN OPIUM POISONING.

---

The interesting contribution concerning the value of permanganate of potassium in opium poisoning which was made by Dr. Thornton and Dr. Holder in the last number of the *THERAPEUTIC GAZETTE* seems to us to settle once and for all the heretofore somewhat doubtful question as to whether the permanganate when given hypodermically exercises any true antidotal influence. Shortly after the suggestion was made that the permanganate of potassium should be given

hypodermically in cases suffering from opium poisoning, we called attention in the editorial columns of the *GAZETTE* to the fact that on theoretical grounds such an administration of the remedy must be absolutely without value, except in so far that the pain of the injection might help to arouse the patient and by keeping him awake enable him to breathe voluntarily, even when the drug had so depressed his respiratory center as to seriously interfere with ordinary involuntary respiration. We pointed out at that time that permanganate of potassium is a substance which when it comes in contact with organic matter very rapidly changes, and that it was impossible for any of the drug, as the permanganate of potassium, to be absorbed into the bloodstream and to oxidize the morphine in the blood or tissues.

These theoretical objections are proved by this research to be correct. It is true that a study of contemporaneous medical literature will discover quite a large number of instances in which physicians have reported cases of opium poisoning which they believe to have been relieved by this form of hypodermic medication. A careful consideration of these reports, however, indicates in almost every instance there were good reasons for patients recovering aside from any effect which the permanganate might exercise. Thus we find in the London *Lancet* of October 30 the report of the case of a man aged thirty-five, who took two tablespoonfuls of laudanum by mistake for "black draught." When seen by the physician four hours after he had taken the poison he was asleep, but was readily aroused, and was given some strong coffee and a hypodermic injection of three grains of caffeine. Later on two more caffeine injections were administered. After this permanganate of potassium was used by the stomach, and to make a long story short, the patient speedily recovered. This is an instance, we think, in which the permanganate of potassium probably produced very little if any effect, and the caffeine was entirely responsible for the good results by reason of the stimulant effect upon the respiratory center. Further, the dose of laudanum was hardly large enough to be fatal in its effects. The temporary delay in the improvement in the man's condition after the first caffeine injection was due to the fact that the drug was not immediately absorbed, and we firmly believe that had no permanganate of potassium been administered in this case an equally rapid recovery would have been obtained.

*THE PRODUCTION OF ANESTHESIA BY SCHLEICH'S MIXTURES.*

The medical profession are now thoroughly familiar with the suggestions made some years ago by Schleich, that weak solutions of cocaine, morphine and sodium chloride should be used hypodermically for the production of local anesthesia prior to minor surgical operations, the advantages of this method being the avoidance of any danger from poisoning by cocaine or morphine, and the effectual benumbing of the sensory nerves in the part which is to be operated upon. Within the last few months Schleich has published the results of his studies upon the anesthetics which are commonly employed by inhalation for the purpose of preventing pain in surgical operations, and he has found that by mixing ether or chloroform with petroleum ether or benzine it is possible to modify some of their physical characteristics and also to alter in some degree their physiological action. The rapidity with which any drug can produce anesthesia by being inhaled is governed in part by its boiling or most rapid evaporation point. The higher this point the greater is its rapidity of action and the more prolonged its effects. Thus we find that in the case of chloroform, the evaporation point of which is 65° C., anesthesia speedily follows its administration in small amounts and lasts for some time. Once in the system it is eliminated slowly because the bodily heat is less than its point of most rapid evaporation. On the other hand, sulphuric ether boils at 34° C., and for this reason acts more slowly and more transiently, because for every breath of ether vapor which is inhaled an equal quantity is exhaled, since its evaporation point is less than that of the body.

Schleich has found that if chloroform, ether, and petroleum ether are mixed they form a fluid the evaporation point of which varies from 38° to 42°, according to the proportions of the ingredients. By the use of such a fluid for anesthetic purposes we avoid the over-effects of chloroform when used alone, the necessity of using excessive amounts of ether, and the patient speedily returns to consciousness after the inhalation ceases. Further, disagreeable after-effects are not so common or severe. These so-called mixtures of Schleich may be made in three ways. No. 1 is composed of:

- R Chloroform, 45 parts;  
Petroleum ether, 15 parts;  
Sulphuric ether, 180 parts.

Its boiling point is 38° C., and as the lower the boiling point the more transient the anesthesia, it is to be employed in brief operative procedures of about twenty minutes' duration. Usually about one ounce or thirty grammes will be required, given best on an ordinary ether cone made of cardboard and a towel. About three ounces will be needed for the period of one hour, in severe operations. If a more prolonged and powerful effect is needed, then one of the following mixtures is used, No. 3 being naturally more powerful than No. 2, because its boiling point is higher. The formula for No. 2 is:

- R Chloroform, 45 parts;  
Petroleum ether, 15 parts;  
Sulphuric ether, 150 parts.

The boiling point of this mixture is 40° C. For No. 3:

- R Chloroform, 30 parts;  
Petroleum ether, 15 parts;  
Sulphuric ether, 80 parts.

The boiling point of this mixture is 42° C.

The petroleum ether is said to have no deleterious effects and seems to modify the effect of the chloroform and dilute the sulphuric ether without altering its general influence. It is to be remembered that only petroleum ether which boils at 60° to 65° C. is to be used. The ordinary petroleum ether, or benzine of the drug stores, which boils at 55° C., is not suitable. Aside from the disagreeable odor of these mixtures, which is a disadvantage, they are asserted to cause less cyanosis, less mucus or other disagreeable effects than any anesthetic known, and to be safer in every way than either ether or chloroform; and they have been tried quite largely with success in this country by a number of surgeons, among whom may be mentioned Dr. Meyer and Dr. Maduro, of New York.

*THE TREATMENT OF GONORRHEA.*

Janet in the *Revue de Thérapeutique* of December 1, 1897, makes a further contribution on this subject. It is extremely interesting because the publication of his first articles has been followed by so many conflicting reports as to the value of the methods he advised that the general practitioner is entirely at a loss to know whether or not these methods are of the faintest service.

Janet states that while we are waiting for some practical results from the sero-therapy which has been investigated by Wassermann, Christmas, Nicolaysen, and Schaeffer, we are

compelled to resort to the most efficient form of antiseptic treatment. This the author holds is by means of copious irrigations with potassium permanganate. Since 1892, when the author's first paper appeared, a paper based on his first cases, he has not written on the subject. His present communication is based on a very much wider experience.

Janet believes that the greatest service he has rendered has been to convince the profession of the folly of the pernicious practise of letting a gonorrhea run. It is to this practise he attributes the vast majority of strictures, cases of sterility, prostatitis, orchitis, rheumatic atrophies, and ankylosis. Efforts at abortive treatment used to be exceptional. In the last year Janet has not seen three cases in which he did not attempt abortion of the disease. In the last eight years he states that he has not had a single case of stricture in patients whom he has seen from the first. He has only seen three cases of orchitis, all insignificant, and has never had an instance of rheumatism, tenosynovitis, conjunctivitis, or any of the other complications of gonorrhea.

Guided by his long experience the author no longer claims that permanganate will necessarily result in rapid cure. He has had to continue his application for two or three months and has given forty and even seventy lavages. He states that at the end of the treatment the urethra will be in as good a state as it was in the beginning, and through the entire course of the treatment the patient is not exposed to any of the ordinary complications of gonorrhea. These prolonged treatments he states are not necessary in more than twenty per cent. of cases, and are due to the fact that extra-urethral and inaccessible gonorrheal foci are established which should be carefully searched for.

With the various agents which have been recommended recently the writer has had but little experience, but with some of them, particularly with argonin, he has succeeded in cases which did not yield to permanganate of potassium.

The armamentarium required for the permanganate treatment is as follows: A quart irrigating bag or vessel provided with a rubber tube nine feet long, on which is placed a stop-cock and in the end of which is fitted a cannula of glass or hard rubber with a blunt conical end; and a method of suspension by means of which the irrigating bag can be drawn to varying heights. This is best done by hanging it on a pulley over the

wheel of which is passed a cord attached to the bag; a urethral syringe to be used for cocaine; a basin; a one-per-cent. solution of potassium permanganate and a one-fourth-per-cent. solution of cocaine; warm boiled water; a graduate for the purpose of measuring solutions; a bed, table or chair on which the patient can either lie down or sit up. It is perfectly possible to practise these irrigations with the patient standing against a wall or supported by a piece of furniture. It must be remembered, however, that on the first irrigation patients often become faint.

Abortive treatment of gonorrhea should be attempted not only from the very first hours of inflammation, but during the first few days, unless the phlegmonous symptoms are extremely severe. The question should be decided rather by the severity of inflammation than by the number of days the disease has lasted. As a rule the treatment of beginning urethritis should be confined to the anterior urethra, which alone is infected; none the less the second urine should always be watched for shreds, and should these appear the complete lavage should be practised.

When the anterior urethra alone is to be washed out the bag is elevated not more than one and a half feet above the level of the penis; the urethra is then forcibly distended, pressing the nozzle into the meatus. This process is repeated until all of the solution is employed, the surgeon occasionally during the course of the treatment clamping the tube of the irrigator and gently milking the urethra from the perineum forward. These irrigations are made twice a day with a quart of 1:2000 solution. If the washings are made rapidly, the cannula having a fairly wide aperture, the weaker solutions are not required. If the washings are made slowly they excite a violent reaction, causing marked congestion; the strength of solution should be lessened to 1:3000 or even 1:4000, increasing to 1:2000 as soon as practicable. After three or four days but one washing a day is administered, but this is so arranged that after the evening irrigation the next one is practised about noon the next day, the following one in the early morning, and thereafter in the morning. These washings are in strength 1:1500, and toward the eighth or ninth day even 1:1000. In cases which do not present traces of inflammation upon the ninth day, the discharge being mucous, almost transparent, the next irrigation should follow

thirty-six hours later and the next forty-eight hours after that. If there is no discharge or a very slight one containing no gonococci, the washings can be omitted, the patient being cautioned to come back for treatment at the slightest sign of return of discharge or unpleasant sensations. If there is recurrence the treatment is resumed, one washing a day, from 1:2000 to 1:1000 being administered, careful search being made for signs of posterior urethritis.

If at any time during treatment the second urine passed shows admixture of pus, the entire urethra must be washed out. To accomplish this the anterior urethra is injected with 1:400 solution of cocaine. This is held in for a minute. The anterior urethra is then washed out with a pint of permanganate solution. The cannula is then pressed firmly into the meatus and the bag is elevated to the height of three and a half feet. The patient is then told to make an effort to urinate, when the liquid will flow into the bladder. The spasmodic contractions which sometimes occur are signs for the momentary withdrawal of the nozzle from the meatus. This posterior irrigation at first may be unsuccessful; sometimes it is only after three or four days that the patient is able to allow the fluid to pass into the bladder. It is occasionally necessary to repeat the cocaine injection during the course of the treatment before the sphincters of the bladder will yield. With gentleness and patience the penetration of the liquid into the bladder can be accomplished in practically every case.

For total irrigation the beginning strength of the solution should be 1:4000, unless patients have been habituated to anterior irrigation. In the latter case, or when the patient is not particularly sensitive, the strength of the solution is the same as that used in the anterior urethra.

Great importance attaches to the time consumed in irrigation. With solutions of equal strength, a washing which occupies six minutes is twice as energetic as one that occupies three. When the washing is practised early, when the urethral inflammation has disappeared, and when very slight inflammatory reaction is excited, patients can be entrusted with the treatment.

Acute and hyperacute gonorrhea will only be encountered in cases which have not been treated by irrigation. Even in those cases Janet holds that an attempt should be made to suppress the discharge by copious flushings. When the anterior urethra alone is

involved success is almost certain, though the ultimate cure is likely to be slow. The first injection should be 1:4000, practised twice a day. These are usually efficacious in promptly alleviating the inflammatory symptoms. When the posterior urethra is infected the treatment is equally satisfactory, provided complete irrigations are possible under the use of cocaine. If it is impossible to practise these irrigations, and this is demonstrated by repeated careful trials, it may be advisable to allow the case to run on until from its self-limiting nature the severe symptoms subside, or to pass a fine Nelaton catheter into the bladder, fill it with weak permanganate solution, and allow the patient to pass it out voluntarily. This should only be practised when patients can be confined to bed, and would be particularly indicated when rheumatism or other general complications are threatened.

The use of sandal is condemned absolutely, Janet holding that he has seen two instances of orchitis develop from this drug. The morning drop is likely to persist for a long time after other symptoms have disappeared.

In the treatment of subacute and chronic gonorrhea permanganate irrigations give results as satisfactory as are the rule when they are adopted in the early stages of acute disease. Satisfactory results are obtained in cases of simple chronic gonorrhea without profound alteration of the mucous membrane, such as is found after repeated attacks or after a fresh infection of old gleet. In a profoundly chronic case accompanied by extensive pathological alterations and yielding a discharge that contains gonococci, results are very far from satisfactory. The treatment of the chronic or subacute gonorrheal discharge consists in administering a series of nine to twelve lavages of permanganate. Sometimes more are required. The irrigation should involve the entire urethra. It should begin with a strength of 1:4000 and this should be increased rapidly to 1:1000, the irrigations always being preceded by an injection of cocaine 1:400. The injections are lessened in number as in the case of acute gonorrhea. It is infinitely better to continue irrigations longer than absolutely necessary, than to allow a discharge to develop again which requires a new series. Sometimes this requires a continuance of irrigations for weeks or months. The most valuable guiding sign as to the possibility of stopping treatment without recurrence of discharge is the disappearance of the gonococci; after this the disappearance of pus and of the

yellow morning drop; finally, the cessation of tickling, itching sensations in the urethra. The shreds in the urine are of little value. The persistence of a mucous or muco-purulent, colorless drop should not prevent the surgeon from stopping treatment.

Before discharging the patient the physician should always endeavor to demonstrate positively that cure is complete. This is especially useful as a means of distinguishing between the relapse of an original inflammatory infection and a fresh gonorrheal infection due to fresh exposure, often with a wife who has been originally infected by the husband and has not been cured. The proof is furnished by causing the urine to become irritating by drinking beer, for instance, or by the results consequent on the first seminal discharge following the cessation of irrigations. The proof afforded by allowing the patient to drink beer should not be attempted for eight days, since recurrence sometimes occurs spontaneously on the seventh day, and if excited by drink is likely to be more severe and more difficult to cure. The patient may take three or four glasses after dinner or even more, and should present himself for examination on the next day and the day following. If no pollutions occur for sixteen days the patient may be allowed to practise intercourse wearing a cover. Provided this is not followed by recurrence of discharge the patient can be pronounced cured. These proofs are only valuable in showing the absence of gonococci after the irrigation treatment.

After a patient is once cured he should be warned that he is especially receptive to fresh infection for two months. He must be warned to avoid every occasion of contracting a new attack of gonorrhea. These patients are also extremely sensitive to infection with other microbes. It is not uncommon for them to develop a purulent discharge without exposure; under the microscope no gonococci are found. Lavage of the urethra with 1:10,000 bichloride solution results in cure.

Independently of all infection it is not uncommon to notice a persistent muco-purulent discharge. If the urethritis preceding this discharge was apparently recent and did not follow upon an old gleet, it is wise to allow this discharge to disappear spontaneously. If it persists for more than two months a complete anterior irrigation of silver nitrate should be practised. After the disappearance of gonococci lavages of silver nitrate, corrosive chloride, and chloride of zinc, and dilata-

tion of the canal with metal sounds or those coated with a pomade, are indicated.

Those who have most conscientiously followed out the modern antiseptic treatment of gonorrhea will be inclined to indorse nearly all of Janet's statements, and to recommend irrigations appropriately modified to each individual case as the safest, the surest, and often the quickest means of curing gonorrhea. His methods of proving cure are, however, to be condemned without qualification. Also, it would be well if he could devise a method by which patients could be induced to regard a perennial non-gonococcal muco-purulent drop with the resignation, even complacency, exhibited by Janet.

## Reports on Therapeutic Progress

---

### *HYPNOTICS: THEIR CONTRAINDICATIONS AND ILL EFFECTS.*

In the *British Medical Journal* of October 2, 1897, MCPHEDRAN, of Toronto, writes an able paper with this title. He says we have so little exact knowledge of the essential nature of sleep and of the precise effects of the various medicines that produce it, or a somnolent state resembling it, that little more can be made than a general statement of the contraindications to and the ill effects of hypnotics.

As to the nature of sleep, some believe that it is an arrest of all the functions of the central nervous system except those essential to life; others that sleep itself is a function. In either case its occurrence is probably largely due to the accumulation of fatigue products—neurotoxin in the central nervous system. How these fatigue products act is uncertain, but probably by interfering with metabolism. The accumulation of waste products may have a paralyzing effect on the protoplasm of the neuron, lessening its affinity for the oxygen of the blood, possibly by diminishing its alkalinity. As a consequence contraction of the neuron or its processes takes place. There is a loss of contact of the neurons as a result of such contraction, and consequently loss of function in the higher nerve centers causing loss of consciousness. In the lower centers resistance is greater, and there is only a diminution of the vital function, as shown by the slower breathing and pulse-rate, and loss of the reflexes.

Of the physiological disturbances causing sleeplessness, our knowledge is no less im-

perfect than that of the cause of sleep. If sleep be due to the fatigue products, sleeplessness can scarcely be due to their absence, because they must be present in increased quantities in conditions of wakefulness. In insomnia there is always disturbance of metabolism with inadequate excretion of waste products, and therefore, also, of inadequacy of nutrition. It is possible that on this account there is a loss of stability in the neurons leading to irregularity in the action of many of them in response to the stimulus of the fatigue products. That there is derangement of the functions of the neurons in sleeplessness the loss of mental power and of general physical well-being amply proves.

The loss of power of compensation in any part can be restored only by lessening the labor and improving the nutrition of the part. The treatment of failure of compensation in the nervous system is no exception to the rule. In insomnia the neurons fail to compensate for the overstrain to which they have been subjected, and in their restoration all agencies which may interfere with the removal of waste products and increase of nutrition, or lessen their stability, should as far as possible be eschewed.

On theoretical grounds, then, it follows that hypnotic drugs are always contraindicated, but in practise it is often best "to do a little wrong to do a great right."

In a general way it may be said that hypnotics should not be used in those in whom the cause of insomnia is palpable and removable. These causes may be briefly summarized as follows:

1. Digestive derangements, whether from improper food and drink, insanitary surroundings, or from whatever cause. In this class are to be included nearly all cases of disturbance of sleep in children, in whom faults of digestion form the bulk of all their ailments. In the adult, however, these same causes play a very, if not the most, important part in the production of insomnia, much greater than they are usually credited with. In the adult the insomnia is, however, less often due directly to the disturbance of the stomach and bowels—that is, due to a reflex cause—than it is in children, whose nerve centers lack the stability of the adult; but it is more often the result of the absorption of toxic agents produced by the ill-digested food in the digestive tract.

2. Local irritations, such as dentition, irritable diseases of the skin, disturbance of the urinary tract. These are also most common

in children. To these may be added reflex disturbances from disease of the uterus and its appendages. Eyestrain is credited with being a frequent cause of insomnia as well as other reflex disturbances.

3. Overwork and the neurasthenic condition resulting therefrom. In the majority of these cases nutrition and excretion play the most effective part, as with a good state of nutrition and due observance of the laws of sleep, overwork is almost impossible.

4. Anxiety and worry. These should be really included with overwork, as they disturb the stability of the cerebral cells in the same manner.

5. Toxic causes are common. Many of them result from derangements of digestion, and are included under that head. Others result from chronic disease—as gout, lithemia, chronic constipation, and Bright's disease. With these may also be included toxemia produced by excessive indulgence in tea, coffee, alcohol, tobacco, and the habitual use or abuse of such drugs as morphine, chloral hydrate, cocaine, etc.

6. A very important group of cases of insomnia is formed by those suffering from disturbed cerebral circulation, whether due to cardiac, renal, or pulmonary disease, or to disease of the cerebral vessels themselves. The blood-supply may be excessive and vascular tension high, as in arteriosclerosis before cardiac compensation fails; or defective and irregular, as in dilatation of the heart. While in some of these conditions the stronger hypnotics are the potent means at our disposal of giving relief, not only to the insomnia, but also to the causes of it, yet in many of them their use would be unwise, and might be disastrous.

7. In not a few sleeplessness is the result of long indulgence in pernicious habits, mental and physical, in regard to sleep, such as irregular hours, various dissipations, the coming over after retiring of the difficulties and reverses, and perhaps the successes, of the day. Such people are loth to believe how much can be done to recover the power of going to sleep at will. It is vain to retail to them the facts of Napoleon, Wellington, and Grant being able to lie down on the field of battle at any time and take a short sleep if needed. They should be encouraged in the effort, and every cause of disturbance removed and such conditions sought as will bring most composure of mind.

In the treatment of insomnia, then, our first duty is to seek out diligently and treat

intelligently such obvious causes as may exist, as: to remedy digestive derangements, whether of stomach or intestines; to stop the ingestion of unsuitable food and drink; to relieve constipation; to stimulate the free elimination of fatigue products; to relieve local irritations and reflex disturbances; to stop overwork and bring the daily duty within the capacity of the worker; to relieve anxiety; to correct as far as possible all disturbances of circulation; to relieve anemic and debilitated conditions; to secure due regard to sanitary requirements; to cultivate good habits of sleep. In all this our aim is to relieve all sources of irritation, direct or reflex, from the cerebral cells, to supply them with ample nutrition, and to cultivate healthy habits in them. Not until these indications are met is the resort to hypnotics legitimate, unless it be to overcome a temporary difficulty; the further use of them is injudicious, if not injurious.

Unfortunately, there is a large class in whom the cause is not easily discovered nor easily removed; or it may be quite apparent and yet impossible of removal. Of such are many cases of neurasthenia, hysteria, and hypochondria. Many of these have a neuropathic temperament, inherited or acquired. In them slight causes, mental or physical, may induce insomnia. Astigmatism may give rise to eyestrain that, though not noticed in health, causes headache or wakefulness in the debilitated condition; or it may be some slight derangement of the digestive system that is sufficient to prevent sleep in the abnormal state of health. Whatever the cause, though it may be very trivial judged by the standard of health, in the debilitated condition of the nerve centers it is often sufficient to produce disastrous effects. In the mental habit that has developed its importance may be greatly magnified. There is a weakness of will power and a ready acquiescence in whatever brings temporary relief, so that the drug or other habit is easily formed and may be difficult to avoid, and once formed, always difficult to overcome.

When, then, should hypnotics be used? In acute disease sleep is often a necessity in order to secure such a restoration of the vital powers as to render recovery of health, or even continuance of life, possible. In sleep, general excitability of the nervous system is quieted, the action of the heart is reduced, and tissue waste is diminished, while more waste products are excreted. All this contributes to improved metabolism and renewed

vitality. So that in the conditions occurring in acute disease hypnotics may be essential; the sleep obtained, though not characterized by benefit to a degree equal to that of natural sleep, is often invaluable. In chronic diseases the same temporary need may arise, but the use of hypnotics in the ordinary conditions of chronic disease is rarely attended by anything but evil. Of the injurious effects of hypnotics on the cells of the central nervous system practically nothing is known. Changes in the nuclei of the cells have been described; they become smaller and more homogeneous, and color more deeply; but we know what interpretation to put on this. While we know nothing of the histopathologic changes, of the physiological effects there is much known in a general way. The author need not stop to detail the injurious effects of morphine, chloral, cocaine, and alcohol.

Of the continued use of the bromides, it might be pointed out that in addition to the general cachexia with loss of appetite, disturbed digestion, anemia, loss of memory, mental apathy, and commencing paralysis and trembling of the extremities that may be developed by their immoderate use, there may occur also marked mental aberration and alarming homicidal tendencies.

Chloralose in three-grain doses has produced alarming collapse in a woman within an hour. Recovery was slow.

The administration of sulphonal is, even in moderate doses, occasionally followed by fatal results. The symptoms set in with abdominal pain and vomiting, scant and usually dark urine, owing to hematuria. Collapse results, soon followed by death. These symptoms may appear suddenly after the patient has been under treatment for some time and has been benefited by the drug.

These effects have been most frequently met with in women with marked constipation. Owing to the constipation there is probably retention of the sulphonal in the system. But serious results have occurred without the existence of constipation to cause retention of the drug. Eighteen grains daily for three days has caused collapse with pallor, weak, rapid pulse, anemia, diplopia, myosis, hyperesthesia, and paresis, the patient being only able to walk with difficulty two weeks later.

In a woman twenty-eight years old, the subject of melancholia and hysteria, thirty grains given in two doses one and a quarter

hours apart caused sleep for twelve hours; then she was aroused. But the somnolence increased, the pupils contracted, and in forty hours death occurred suddenly.

Hematorporphyrinuria is supposed to be due to gastro-intestinal hemorrhage. In dogs killed with sulphonal active and passive congestion of the meninges has been found, with, in some cases, hemorrhages at the floor of the fourth ventricle.

Marked congestion of the spinal cord and degeneration of the nerve cells of the anterior horns of its lower portion have also been found.

It is evident that greater care is necessary in the administration of this drug than has generally been observed. The laity are coming to look upon it as a safe hypnotic, and many use it without restriction.

The continued use of trional tends to give rise to various disturbances of consciousness, of speech, of hearing, and of vision, to loss of memory, and to ataxia of movements in general. There may be involuntary excretions of urine and feces. To prevent these untoward symptoms its use should be intermitted from time to time.

Paraldehyde is a comparatively safe hypnotic, yet large doses of it have been followed by serious effects. Great dyspnea and collapse have resulted from one drachm in a case of chronic bronchitis. Somewhat larger doses have caused marked delirium with paresis of the functions generally, resembling delirium tremens of alcohol.

The proneness to the formation of a confirmed habit is a strong reason why any hypnotic should be used carefully and with due appreciation of the needs of each individual case. And this propensity to form the drug habit is especially marked in neurasthenics, the very class from which the cases of insomnia are most largely drawn.

In neurasthenia and in conditions of unstable nervous or physical equilibrium, whatever develops or creates self-discipline and self-control in the patient is of great value. Such self-discipline is interfered with by hypnotics.

In some conditions the amount of narcotics necessary to induce sleep is so great that it is better to let the patient lie awake for two or three nights even than to give such large quantities.

If power of compensation is lost, it cannot be restored by any means other than by lessening the labor and improving the nutrition of the parts that have failed. It would

seem eminently unfitting in such a condition to resort to medication that interferes with digestion and assimilation and retards the processes of elimination, when the hope of cure must rest on restoration to a healthy metabolism.

It is wise practise to give hypnotics rarely, and only when other means have failed; then only in the smallest dose necessary to give sleep, being satisfied with the least amount of sleep that is safe.

#### CASES OF GENITO-URINARY DISEASES TREATED BY KAVA KAVA.

LESLIE PHILLIPS writes on this topic in the *Edinburgh Medical Journal* for August, 1897. He begins by expressing the hope that a brief record of results obtained from a clinical inquiry into the action of kava-kava in genito-urinary cases may be of value, particularly as his results do not in some respects coincide with those of previous inquirers. The preparation used was the fluid extract of the root prepared by Messrs. Parke, Davis & Co. The dose given was one drachm thrice daily, largely diluted with water, and the observations were not complicated by the simultaneous use of, or combination with, other drugs, as the author notes is the case in not a few of those published cases in which benefit is ascribed to kava. The general results obtained are here given, and a few only of the cases are given in short detail. Kava appears to have won its best reputation in acute or recent gonorrhea. In the author's experience these are the cases which benefit least from its use.

The following case stands in sharp contrast to the second, in which the drug used early in the acute stage of gonorrhea appeared to produce the complication which in the present case it cured.

Gonorrheal epididymitis; rapid beneficial action of kava-kava: Alfred H., in the fifth week of a gonorrhea, was attacked with a left acute very painful epididymitis, attended with complete subsidence of the urethrorrhea. Kava-kava was ordered. He went about his work as usual, and no local application was ordered. Three days after he began to take kava the discharge reappeared in moderate quantity, and the pain in the testis was relieved. In one week the swelling had very largely subsided, and in fourteen days the testis was of normal size, though a little indurated.

The author has not found kava of use in sexual debility, with frequent nocturnal emis-

sions—that class of cases often labeled “spermatorrhea”—nor in chronic cystitis due to prostatic obstructive disease. In a case of gonorrheal rheumatism it produced at first a decided diminution of the pain, but the effect was evanescent.

#### THE PRODUCTION OF PLASMATIC CELL JUICES FROM THE LOWER GERMS.

H. BUCHNER delivered an address before the Medical Society of Munich on November 10, 1897, based on researches conducted at the Hygienic Institute of the University of Munich, in which he stated that during the course of the past year certain results of interest had been obtained. In the first place Professor Edward Buchner, of Tübingen, succeeded, with the material assistance of Dr. M. Hahn, in developing a method which secures the cell juices of the lower germs practically unmodified. Briefly described, this method consists in mechanical trituration of the moist germ-mass admixed with infusorial earth and fine quartz sand, followed by expression of the doughy mass under hydraulic pressure of 400 to 500 atmospheres.

The first experiments were made with compressed yeast, from one kilo of which was obtained 500 cubic centimeters of a clear, yellowish, slightly opalescent liquid, which on heating coagulated almost *in toto*, and hence possessed a large percentage of coagulable albumen as it occurs in the animal organism. This is a new discovery, for while the lower germs were previously known to contain albuminoids, the presence of true albumen has never until now been demonstrated.

Very remarkable also is the presence, first observed by M. Hahn, of powerful digestive enzymes in the expressed juice of yeast—enzymes which must plainly owe their origin to the yeast cell. To their activity must be attributed the striking fact that the abundant quantity of albumen in the yeast cell juice disappears quite rapidly at the temperature of the incubator, even when, by the addition of an antiseptic (as, for example, chloroform) the development of living germs is completely excluded. We accordingly have here a species of autodigestion which can be ascribed to nothing else than the action of enzymes.

Another phenomenon of fundamental importance was observed by Edward Buchner in the expressed juice of beer yeast—the

*development of genuine alcoholic fermentation without the presence and cooperation of any living organism whatsoever.* All that is necessary is to add a little sugar solution to the clear juice (should the juice not be clear it is to be clarified by passing it through filters of “kieselguhr” or porcelain); bubbles of carbonic acid appear at once, or after five to fifteen minutes, according to temperature, and the fermentation continues in the same intensity for days. This phenomenon, which at first provoked many doubts, has now been established by oft-repeated experiments, and has been sufficiently studied in a chemical light to be regarded as a positive datum. We are thus taught that in the process of fermentation it is not the vitality of the yeast cell as such that accounts for the chemical changes; rather these changes must be ascribed primarily to a special enzymic substance contained in the yeast cell.

This enzymic substance, which has been named *zymase*, is of course the product of the yeast cell, but is capable of exerting its action after it has once been elaborated independently of the living cell. A remarkable fact is its susceptibility to extraneous influences. Very slight exposure to warmth is sufficient to destroy its activity, whereas antiseptics, such as one- or two-per-cent. solutions of arsenite of sodium, which are very injurious to the living cell, have but little influence upon it. Again, the action of *zymase* is extinguished when the expressed yeast juice containing it is stored for even a short time. This fact, in conflict with earlier views, is probably due to the process of autodigestion already mentioned. Dried *zymase* is permanently active. It can be precipitated from the expressed yeast juice with alcohol and can be isolated to a certain degree of purity.

After it had been shown by these experiments that the new method really permitted us to obtain the contents of germ cells in unmodified and active form, the thought at once suggested itself that the new method might also be applied to bacteria, especially the pathogenic species. Since new and previously unknown properties had been observed in the expressed juices of yeast cells, there was ground for the hope that special and specific properties would be encountered in the expressed juices which might be prepared from bacteria. The task thus outlined (in which, of course, many technical and biological difficulties remained to be overcome) fell naturally to the lot of Dr. M. Hahn, in-

asmuch as he had done so much in the elaboration of the general method, and his results are given in the following paragraphs. Buchner merely mentions that he has selected for the plasmatic cell juices of the various lower germs, obtained by the new method, the common and comprehensive designation of "Plasmins." This name indicates that we have to deal in all these cases with albuminous plasmatic liquids. Individually they are to be differentiated under the names of "typhoplasmin," "cholera-plasmin," "tuberculo-plasmin," etc.

With the tuberculo-plasmin Buchner and Hahn have treated a series of guinea-pigs, previously infected with a pure culture of tubercle bacilli or with the human sputum containing bacilli. In most instances the treatment was begun two weeks after infection, with very small doses, gradually increased. The animals reacted distinctly in every case, in the main with moderate but often with more pronounced symptoms of fever. The treatment was continued for months.

Of the large number of animal tests we will single out only those which can be regarded as truly demonstrative—that is, those in which the control animals, infected at the same time and in the same measure, succumbed more than one and a half months ago to pronounced general tuberculosis. The other series of tests are not mentioned for the reason that as a result of the behavior of the control animals they can attribute to these tests for the present no absolute demonstration of power. Only twenty-three animals are to be considered. Of these, six were control animals. These six animals succumbed within one and one-half to four months after infection to a pronounced disseminated general tuberculosis. Out of seventeen animals treated with tuberculo-plasmin, five yielded absolutely negative results—that is, they died after being treated two to three and a half months; autopsy showed pronounced general tuberculosis, without any modifications which might indicate a curative process or warrant the inference that the dissemination of the tuberculosis had been visibly impeded. Three of the treated animals died within the first one and a half months of treatment—some within the first fourteen days; and in view of the shortness of the space in which they received no treatment at all Buchner and Hahn are not in a position to use these animals for statistical purposes in either a positive or a negative

sense. Four animals showed partially positive results—that is, they died after several months of treatment, exhibiting in their organs tuberculous modifications, but the dissemination of the tuberculosis was less marked than in the control animals, the lung lesions being less pronounced, or not at all invaded. Further processes were perceptible which pointed to cure, notably a marked formation of connective tissue in the neighborhood of the tubercle. Five animals yielded an incontrovertible, positive result, inasmuch as they are to-day alive, whereas the control animals succumbed one and a half to two months ago.

If we consider the great susceptibility of the guinea-pig to tuberculosis, as well as the potency of the injection employed, we must admit that the results obtained—the preservation of almost one-third of the injected animals—cannot be termed an unfavorable showing. And Buchner and Hahn cannot avoid referring these results to a certain specific action exerted by the tuberculo-plasmin on the tuberculous infection; for the natural power of resistance in guinea-pigs is *per se* a very slight one and seems to be susceptible of augmentation only within very narrow limits—for example, by the production of hyperleucocytosis.

Buchner and Hahn are by no means of the opinion that tuberculo-plasmin is a remedy suited to all cases of human tuberculosis. The issue of the experiments thus far made seems rather to support the view that experimentation with the remedy at the bedside would be justifiable. The clinical experiments thus far made, although few in number, have at least established the harmlessness of the remedy when carefully administered. Buchner and Hahn feel that they ought to lay stress on the fact that it is possible with their process to obtain the cell contents of tubercle bacilli in a relatively easy and harmless manner as well as in a form which renders possible therapeutic employment.

It is not, however, to be expected that the results in the human patient will be as great as those obtained in the tuberculosis of guinea-pigs. The pulmonary tuberculosis of human beings usually presents itself for treatment in a comparatively much more advanced stage; it exhibits great individual fluctuations and frequently secondary infections. All these facts combine to form a more highly complicated morbid process than that which confronts us in guinea-pigs—which tends to baffle the correct application

of a specific remedy. Again, it must always be remembered that the guinea-pig receives per gramme of body weight much more specific substance than is ever the case in the human being; for considerable difficulties will always confront the single injection of large quantities of such a remedy. In the small doses, however, which can be injected into human beings, there is certainly always present a small quantity of specific substance; and if it be desired, so to speak, to impregnate the diseased organism by specific substances, it will be necessary to resort to frequent injections which must be prolonged for months, beginning with small doses and gradually increasing the quantity of each injection. Under such treatment the tuberculo-plasmin will also produce a non-specific action—hyperleucocytosis—whose favorable influence on experimental infection has been reported from various quarters.

#### GELATIN AS A HEMOSTATIC.

The carpenter's time-honored recourse to the glue-pot in case of cut fingers and the like has lately received scientific justification at the hands of Dr. PAUL CARNOT, an interne of the Paris hospitals, who treats of gelatin as a hemostatic in *La Presse Médicale* of September 18. He divides hemostatics into two great groups—those that, like ergotin, constrict the vessels and retract them, leaving to spontaneous coagulation the work of obliterating the openings, and those that, applied locally, hasten coagulation, such as perchloride of iron, the salts of calcium, gelatin, gelose, etc.

There are several objections, M. Carnot thinks, to the vaso-constrictor hemostatics, such as ergotin, pyoktanin, and extract of suprarenal capsules. In the first place, most of them are very poisonous. In the next place, when coagulation takes place in a retracted vessel, the clot is strained and apt to be torn on the return of the vessel to its normal caliber, thus occasioning a recurrence of bleeding. Moreover, the arterial pressure is augmented, and that is an unfavorable condition if many vessels are involved. Finally, general vaso-constriction facilitates infection in an organism weakened by hemorrhage. With regard to this point, he cites Bouchard and Charrin as having shown that vaso-constriction is a weapon in the hands of micro-organisms at the time of their implantation, and that the system reacts by setting up vaso-dilatation, which favors diapedesis and

the diffusion of defensive juices. Recent experiments, he adds, have shown that at the beginning of an infection it is of great importance to effect vascular dilatation; if rabbits infected with a fatal dose of such cultures as that of Eberth's bacillus, for example, are made to inhale amyl nitrite at once, they survive, whereas the test animals perish in a few days. For these reasons, M. Carnot thinks the use of vaso-constrictors should be restricted to cases in which the hemorrhage is insusceptible of topical treatment.

The hemostatics of the second group—the coagulants—on the other hand, he says, do but exaggerate the natural hemostatic process. The coagulation of blood outside the vessels plugs them efficiently in the majority of cases, but it fails if the wound is too large or if the blood is so altered that its coagulability is impaired, as in animals poisoned with peptones or leech extract and in cases of hemophilia. The author adds the interesting observation that he has seen two dogs under the influence of peptones die of intestinal hemorrhage caused by ascarides. But there are grave objections to most of the coagulants that are in common use, says M. Carnot, especially to perchloride of iron. A few of them, however, are well-nigh harmless; they are the salts of calcium, especially the chloride, and gelatin and gelose.

It seems that the coagulant property of gelatin was discovered by Dastre and Floresco, whose report of experiments was made to the Society of Biology in February, 1896, and published in the *Archives de Physiologie* for April of that year. They were properly careful to distinguish between coagulation and gelatinization, and they found that an amount of gelatin that was too small to cause gelatinization augmented the coagulability of the blood. But M. Carnot thinks that both properties, the coagulating and the gelatinizing, are of value in bringing about hemostasis, and it is their association in gelatin that makes him prefer that substance to calcium chloride. Since gelose gelatinizes at a temperature higher than that of the human body, he adds, it is still more useful. Experiments have shown him also that both gelatin and gelose play the part of nutrients in a wound and hasten its healing.

M. Carnot states that he has used gelatin both as a local hemostatic and to modify the coagulability of the blood as a whole. As a local hemostatic, he employs a solution of gelatin in water, or better, in the physio-

logical (seven to a thousand) solution of sodium chloride. This is sterilized by keeping it at the boiling point of water for fifteen minutes at a time on two occasions, two days apart. The temperature should not be raised to 239° F., for that sometimes destroys its gelatinizing property. The strength of the solution varies according to the end in view; generally it is from five to ten per cent. An antiseptic may be added without impairing the coagulating and gelatinizing properties of the solution, but it is only in special cases that he does it, for one of the advantages of gelatin is its harmlessness.

It was in comparatively simple cases that M. Carnot first tried gelatin, such as those of rebellious epistaxis in children affected with hemophilia. In one such case the child was almost bloodless, having several attacks of nosebleed daily. Antipyrin, perchloride of iron, and other applications had been used without success. The nostril from which the blood proceeded was injected with thirty or forty cubic centimeters of a five-per-cent. solution of gelatin, and a tampon wet with the same solution was left on its orifice. The hemorrhage stopped at once. On the following day bleeding took place from the other nostril, and it was stopped in the same way. There was no more epistaxis, but the child had in succession purpuric, intestinal, pericardial, and other hemorrhages, and at the time of its death it had only 365,000 red corpuscles left (to the cubic millimeter of blood, we presume). The treatment, then, was efficient locally, says M. Carnot, in spite of the great alteration of the blood.

M. Carnot recommends that the solution be not used too hot, partly because gelatinization would thereby be retarded, and partly because the gelatin acts only by contact with the blood; the energetic vascular constriction produced by the heat would arrest the hemorrhage for an instant, but blood and gelatin being no longer in immediate contact, no plugging clot would be produced. It is better, he says, to use a solution of about the temperature of the body. The mode of application is the same for any hemorrhage from a cavity readily accessible. For cutaneous wounds, and particularly for those of the fingers and hands, M. Carnot has frequently used solutions of gelatin. He simply moistens the wound with a few drops of the sterilized solution, and leaves on it for a few minutes a pledget impregnated with the same solution. Hemorrhages from ruptured varices and those from the rectum are

amenable to the same treatment, but hemorrhages from the stomach are not, for the gastric juice at once transforms the gelatin.

In cases of uterine hemorrhage, says M. Carnot, the application is a little more complicated, for the necessity of direct contact between the gelatin and the bleeding vessels requires the injection to be intra-uterine; hence it should be done with all known precautions, and especially with sterilized solutions and aseptic instruments. The author has thus far employed the treatment in only one case of metrorrhagia, due to a fibroma, and in that he was perfectly successful. He has often used gelatin water in place of hemostatic forceps, and has found it sufficient to hold tampons wet with the solution against the bleeding points for a few seconds.

Incidentally M. Carnot relates an interesting case of the successful replacement of a severed part. A young workman had the last joint of one of his fingers detached by a clean cut. About half an hour after the accident the author saw him at the Hotel Dieu. The young man had the end of his finger in his pocket, carefully done up in paper. The wound was bleeding very freely. The bleeding was arrested immediately by the application of a solution of gelatin stronger than that usually employed. M. Carnot then applied the detached portion of the finger, and kept it in place by wrapping the whole digit with iodoform gauze and then with strips of sticking-plaster. The man came back at the end of two days, when the severed joint was neither decomposed nor desiccated. Very curiously, says the author, the patient could feel quite a slight pressure on the end of the finger, but it had no sensibility to heat or to pain; perhaps, he adds, the sensation felt was only transmitted to the line of section. The "graft" was finally successful.

It is only on the lower animals that M. Carnot has tried gelatin in the more difficult problems of hemostasis. In experimental resections of very considerable portions of the liver, he says, he soon renounced all sorts of ligation, and now contents himself with a few seconds' contact of the gelatin solution with the bleeding surface, even taking pains not to make any pressure in applying it. As soon as a clot has formed and the surface ceases to bleed, the liver is replaced in the abdomen; generally a few cubic centimeters of the gelatin solution is poured into the peritoneum before the abdomen is closed, to guard against the danger of recurrent

hemorrhage; and he has never known death from bleeding to follow.

M. Carnot speculates about the use of gelatin in the case of a large wounded artery. After division of the carotid, he says, it would evidently have small chance of proving efficient; nevertheless, combining it with clamping of the vessel for a few minutes would perhaps give the clot time to adhere solidly enough to resist the arterial pressure, and thus do away with the necessity of leaving in the wound threads difficult of absorption.

As regards the use of gelatin for the purpose of enhancing the coagulability of the blood in its totality, M. Carnot can speak only with great reserve. Intravenous injections of gelatin in the human subject he thinks unwarranted, owing to the danger of producing massive clots. In several instances, however, he has injected gelatin subcutaneously and into the rectum with success. In a "bleeder" the spontaneous hemorrhages were thus made to cease; in another case purpura was caused to disappear rapidly. But the author says that he has been too much restrained by fear of rendering the coagulability of the blood too great to generalize concerning these results.—*New York Medical Journal*, Oct. 23, 1897.

#### ANTIPYRIN AND LACTATION.

After various researches made by M. G. Fieux, says a writer in the *Bulletin Médicale* of September 5, 1897, he reached the following conclusions:

1. Antipyrin certainly passes in a natural state into the milk.

2. Given in large doses, in two capsules each containing fifteen grains at intervals of two hours, it may be detected in the milk in from five to eight hours after its ingestion, and from nineteen to twenty-three hours afterward it cannot be discovered, so elimination lasts eighteen hours at the maximum.

3. The antipyrin during this time passes into the milk only in an excessively weak proportion, very much less than fifty parts in a thousand; it is only in exceptional conditions—for instance, when sixty grains are administered in sixteen hours—that it perceptibly reaches this proportion.

4. It does not influence in any way the quality of the milk and, particularly, the lactose, the casein, or the fat.

5. It seems to have no action at all on the secretion, which always remains very

abundant, provided the woman continues to nurse.

6. From the absence of general symptoms and from examinations of the weight, the infinitesimal quantity absorbed by the nursing does not seem to have any unfavorable action.—*New York Medical Journal*, Oct. 23, 1897.

#### DEATH AFTER WORMSEED.

Dr. A. K. BOND reports a death due to an excess of wormseed, in the *Maryland Medical Journal*, August 7, 1897.

The patient, a boy about three-years of age, complained of "stomach-ache" for several days. His ignorant mother made a diagnosis of "worms," although no worms were at any time seen in the stools, and going to the drug store purchased of the clerk a quantity of wormseed oil.

On the same night (June 28) she gave the child ten drops of the wormseed oil on sugar. Not all of the sugar thus medicated was taken. Next day the bowels were freely moved, no worms appearing, and no odor of wormseed being noticed in the stools.

On the morning of June 30, half an hour before breakfast, the mother gave half a teaspoonful of the wormseed oil undiluted. Half an hour after breakfast the patient vomited twice and went into a stupor. The mother being frightened sent for Dr. Bond. On arrival, he found the patient lying quiet, but he could be aroused by rough shaking. The eyes were closed, the pupils small but equal; the pulse and respiration normal; no fever present. Vomiting was secured twice by salt and water, the water coming up clear. The author gave one grain of calomel and ordered repeated half-teaspoonful doses of castor oil at perhaps hourly intervals.

At midday the pulse was 96, the respiration 48, with snoring breathing and much mucus in the mouth, sweat on the face, deep stupor, and beginning twitching of the right hand. The pulse soon rose to 120. No urine had passed since the morning dose of the wormseed oil was given, and there seemed on external physical examination to be little or no urine in the bladder.

At 1 P.M. slight passages were procured by an enema, which smelled of wormseed; after which brandy was thrown into the bowel. The pupils at this time were equal and not unnaturally dilated. The mouth and hands twitched occasionally. There was deep stupor, from which the patient could not be aroused. The body was comfortably warm

At 3 P.M. the pulse was 128, the respiration 56, rattling as before, and diaphragmatic. There were large râles in the left side of the chest and little or no respiratory movement on the right side. No urine yet passed; sphincters holding; deep stupor. The spasmodic twitchings had ceased. Hot external applications were ordered, but it was evident that death was setting in. The patient died at 4 P.M. of this same day (June 30).

Two questions naturally suggested themselves: Is oleum chenopodii liable to produce fatal poisoning? and, if so, was the fatal issue in the case just related due to the administration of this drug? Upon the first point authorities are strangely at variance. The use of wormseed oil is wholly confined, as far as the author can learn, to North America. European writers do not speak of it, simply because it is in Europe unknown to the profession or public. The plant from which wormseed oil is obtained, the *Chenopodium anthelminticum*, is a native of North America, and began to be used as a vermifuge soon after the discovery of this continent. It grows very abundantly as a rank weed about country residences, and Baltimore is the chief center for the manufacture of its oil. It is a favorite domestic remedy in country families, prepared freshly by the women of the family for each occasion. When a child, in the family is supposed to "have worms"—namely, round worms, ascarides lumbricoides—the yard about the house is searched, and without difficulty some of the weeds are found. A handful or two of the seeds are rubbed off the weed and dropped into a vessel. Boiling water is now poured on the unbroken seeds and allowed to cool; it is then poured off the seeds, sweetened with molasses, and given to the child in indefinite quantities until worms are passed, or until the child improves in health, or until the mother decides that her diagnosis was mistaken. Sometimes it fetches worms, being rendered aperient by the molasses or by subsequent cathartics. Even if no worms are brought to light, the child usually improves in health from some cleansing or tonic action of the wormseed tea on the digestive tract. As the tea is believed to be harmless, no definite quantities of the seed or of the tea are observed.

The oil of wormseed, prepared by the manufacturing pharmacists, is a much more powerful drug. Plain country people are somewhat afraid of it, as it is credited with occasional severe or fatal effects.

American writers on therapeutics seem to consider the plant and its preparations practically harmless.

Waring's Therapeutics, 1866, quotes Dr. Dewees as saying that it is a good anthelmintic (for round worms, of course), but that preexisting fever is a contraindication. No warning of any danger from its use is given.

Mitchell's Therapeutics, 1850, speaks favorably of its uses from hearsay, but gives no warning of danger.

Eberle's Therapeutics, 1847, speaks highly of it, and says that we may give an electuary of the powdered seeds in syrup in the morning before eating, and again some hours after supper; or may give of the wormseed oil to a child two or three years of age three to eight drops twice a day in sugar or mucilage, and after it has been taken thus for three or four days should administer a brisk purgative. No hint of danger from the remedy is given.

Bartholow's Therapeutics, 1880, gives a very brief description of the agent: that it increases the action of the heart, skin, bronchial passages, and kidneys, being a diffusible stimulant. Here also no note of warning against possible injurious effects is given.

H. C. Wood's Therapeutics, 1891, states that the oil becomes darker and less fluid with age; that it is very efficient against round worms; that the dose of the wormseed oil is ten drops, to a patient three years of age, given on sugar before each meal for two days, followed by a brisk purge. No warning is given in the text against harmful possibilities. In a foot-note a reference is made at some length to a case reported by the late Professor T. R. Brown, of the College of Physicians and Surgeons of Baltimore, in the *Maryland Medical Journal* for 1878, vol. iv, pp. 20-28, in which a fairly healthy young man died two days after taking an ounce or more of wormseed oil. The foot-note closes with the remark: "It is plain that the wormseed was not the direct immediate cause of all these symptoms (related in the case report) or of the fatal result."

Foster's Dictionary of Therapeutics gives no warning that the chenopodium is in any way dangerous or that overdose is to be avoided.

#### FORMALDEHYDE AS A DISINFECTANT.

In the *New York Medical Journal* of October 16, 1897, DOTY gives the results of a careful study of formaldehyde as a disinfectant. He concludes that a careful analysis

of the results obtained in this experimental investigation to determine the value of formaldehyde as a disinfectant shows that this agent cannot be depended upon for disinfection where deep penetration is required. It can, however, be relied upon to penetrate letters and other thin packages if placed in an air-tight chamber. It is here that the importance and value of a vacuum is appreciated. Packages of the character just described are usually penetrated in a comparatively tight room. This has been proved not only by the germicidal effect upon the micro-organisms contained, but by the effect on blotting-paper, ribbons, and silk, colored with fuchsin and magenta, and placed inside of letters, the envelope being tightly sealed. The change of color is very apparent upon opening the package after treatment. In packages made of blankets, clothing, etc., the action of formaldehyde upon infected disks placed inside is uncertain and not always the same. As a rule, penetration does not occur; at least the organisms are not generally killed. This uncertainty would seem to decide the inefficiency of formaldehyde for deep penetration. For superficial disinfection—*i.e.*, of hangings, furniture, clothing, furs, silks, and other articles which can be spread out and the surface exposed—formaldehyde is an agent of undoubted value, particularly as it does not, as a rule, injure the finest fabrics, and therefore may be safely used in an apartment furnished with delicate paper-hangings and furniture.

In the selection of the method for disinfection with formaldehyde, it is evident that the use of a formaldehyde solution simply exposed on pans is not to be considered, provided other methods are available. The heating of pastilles of paraformaldehyde is a simple, effective and neat method of securing the gas, although at present it is a comparatively expensive one. It is necessary, however, that the apparatus for heating the pastilles should remain in the apartment until the time for disinfection has expired. The gas is therefore evolved slowly and its release depends upon the proper performance of a lamp which cannot be kept under observation. For the same reason it may not burn sufficiently long to reduce the pastilles to ashes, or an accident may happen. These are only possibilities.

The lamp for the generation of formaldehyde by the oxidation of methyl alcohol is also an effective method. This method of securing the gas is considerably cheaper than

the preceding one—a pint and a half of wood or methyl alcohol, valued at twenty cents, being sufficient for the disinfection of a room having a space of one thousand cubic feet, whereas the expense of the pastille for this purpose is about seventy-five cents. Like the apparatus just described, the lamp can be purchased for a comparatively small sum, is easily manipulated, and is very satisfactory for house disinfection. However, it is practically subject to the same criticism—*i.e.*, that the process is comparatively slow, and the lamp remains in the apartment, and not under observation, until the disinfection is completed. In a structure subject to change of position, as a ship, it is not improbable that an accident might occur.

---

#### THE TREATMENT OF ECZEMA WITH PICRIC ACID.

In an article on this subject in the *Nouveau Montpellier Médical* for September, 1897, M. A. BROUSSE remarks that the kerato-plastic property of picric acid, which has been successfully used in burns, seems to indicate that its employment is proper in the treatment of eczema, certain forms of which present great analogies to superficial burns. In 1889, he says, Cerasi employed this drug in seven cases of eczema with excellent results. Dr. McLennan, of Glasgow, was also very successful in the treatment of acute eczema and eczema of the face with this drug, which he used in a saturated solution. The author himself has obtained rapid recovery in several cases in which he has employed this treatment, the histories of which are given in detail. In cases of lichenoid eczema with a thick epidermis the acid was useless, but in acute oozing eczema accompanied by edema of the skin it was very useful. Under its influence in one case recovery was obtained in two weeks; in another case, in ten days.

Among the advantages of this treatment are the immediate relief produced by the application of the picric acid solution and the disappearance of the pain, heat, and itching; the rapidity with which edematous tumefaction is effaced; and the absolute painlessness of the dressing, even when it is applied to the bare surface of the derma. According to the opinion of the most competent observers, the extensive application of this drug does not give rise to any symptoms of poisoning. Not only is it useful in acute eczema, but it is also useful in acute attacks

of chronic eczema which are so frequent in arthritics, particularly if they are accompanied by oozing and ulceration of the skin; it is equally useful in the seborrheic eczema of infancy. The author states that the results obtained by him with this treatment absolutely confirm those indicated in the publications of Dr. McLennan, M. Gaucher, and M. Leredde.

M. Brousse therefore concludes that this treatment is indicated as follows: (1) In acute eczema; (2) in the acute attacks of chronic eczema, particularly if there is a tendency to oozing and ulceration of the skin; (3) in the seborrheic eczema (impetiginous) of infancy. This treatment, he says, is contraindicated in chronic eczema and generally in all those forms of eczema which are accompanied by a thickening of the epidermis (lichenoid eczema). Nevertheless, it has the advantage, even in these cases, of allaying the itching.—*New York Medical Journal*, Oct. 16, 1897.

#### NOTES ON THE TREATMENT OF STATUS EPILEPTICUS.

L. PIERCE CLARK in *Pediatrics* of August 15, 1897, tells us that since the opening of the Craig Colony for admission of epileptics many cases of status epilepticus have occurred, but as yet no deaths have taken place from the same. Many remedies have been tried; chloral in large doses (forty to eighty grains) has been given, but little real benefit has been obtained from this drug even when it has been given alone and in very large doses. It is a powerful sedative upon the whole vascular system, and especially upon the heart. It cannot but be productive of great harm when given in very large doses, for at such times the heart is probably laboring under a heavier burden than it is ever called upon to bear in any other affection; therefore chloral should be given with extreme caution.

It is difficult to see how emetics can be of any value, offering as they do great hindrance to normal respiration. Occasionally drugs having this action have been administered, but they have been much more productive of harm than good.

Although chloroform is spoken of by many writers as being only "palliative," yet it can often be employed with great advantage if used with caution, and only at such times when the seizures are about to begin. It must never be given at the sleep or stupor

stage, as at such times it may cause deep coma and even death. The so-called "palliative treatment" is frequently of the utmost importance; in fact, the palliative treatment is about the only one which is of any great service in treating status epilepticus, therefore chloroform should be tried in all obstinate cases. Morphine has proven of some value when used in conjunction with other drugs, but used singly it shows a very uncertain action in epilepsy, so much so that its benefit or failure in any particular case cannot be proven until it is tried.

Nitrite of amyl is a remedy often spoken of with great favor, but the writer has never seen a case in which its administration was a benefit; on the contrary, he has often seen it do positive harm, even provoking or prolonging an attack. From his experience its disuse cannot be too thoroughly recommended. He has seen epileptics who have been supplied with nitrite of amyl pearls or small vials of the drug, which the patients have been instructed to carry in their pockets in order that they might use it whenever an aura occurred. Frequently such cases are automatic and are almost certain to perform many semi-unconscious acts which they would not otherwise do were they in a normal state. While patients are in such a state the writer has seen them upon the point of swallowing enormous doses of the drug, which if a nurse had not prevented them from doing would have been productive of fatal consequences. Again, reasoning upon the physiological action of nitrite of amyl, its use would seem to be extremely limited in all epileptic conditions.

It is but fair to say here that in such an institution as the Craig Colony, where the proper food, exercise and hygienic surroundings are obtained, the manifestations of status in epilepsy are less severe and much more amenable to treatment than cases occurring in a physician's private practise.

The writer has not tried the various remedies recommended for status epilepticus without making some observations and experiments of his own. The prescription which will be given with this article has undergone various modifications from time to time, until it now seems to have become sufficiently crystallized to report for trial away from the Colony. No cases of status have occurred as yet at the Colony where it has not been possible to give this remedy by the mouth; indeed, all medication for status should be given at such times as the drug can be

taken by the mouth. To any one unacquainted with the conditions of status the writer cannot urge too strongly the great necessity of the very earliest treatment possible; half the terrors of status are removed when we recognize that it is a condition demanding immediate action. If the condition is cared for at an early moment the whole organism is in a fair condition to respond to the drugs which may be given; but if delayed, enormous doses of chloral bromide and morphine may be given without any result whatever. After treatment has been instituted by the prescription which is here given, almost all cases of epilepsy have had no seizures following its administration. In a few, two or three attacks have occurred for the first fifteen or twenty minutes after its administration, but no longer. The prescription is as follows:

R Tinct. opii deodoratæ, 5 minims;  
Potassi bromidi, 25 grains;  
Chloral, 20 grains;  
Liq. morph. sulph., 1 drachm.

M. Sig.: One dose; repeat in two hours if necessary.

An explanation of the efficacy of this prescription might be hazarded on the following principle: The chloral and morphine are the first to act in their respective order, the chloral as a sedative upon the vascular system and especially upon the blood-supply in the brain; the morphine as a sedative on the nerve cell. Following their immediate combined action we get the slower and more permanent effects of the bromide and opium upon the cerebral centers.

#### TREATMENT OF BURNS.

MARIE B. WERNER in the *Polyclinic* of October 30, 1897, advocates the following treatment for burns, which is simple and appeals at once to the ordinary reasoning mind:

1. Place the burned member or surface in a carbolized bath of from two to five per cent., depending on the age of the patient and the extent of the injured surface. A threefold effect is gained by this—*i.e.*, anti-sepsis, asepis, anesthesia.

2. Remove all the acid solution by a second bath in the physiologic saline solution.

3. Dust the entire surface with a powder containing acetanilid (one part) and compound zinc stearate (five parts).

4. Cover surface with narrow strips of Lister's green protective, or, if economy must be studied, thin gutta-percha tissue can be used instead.

5. Place wet sublimated gauze ten to twenty thicknesses over and around the surface, followed by ordinary bandaging.

The subsequent dressings differ only in one or two points from the first, as stated above. The carbolized bath is substituted by one of either the saline solution or a weak solution of mercury bichloride, followed by a spray of hydrogen dioxide which will aid in removing all the pus and loose dead tissues; after this, the surface is dusted with the powder, and protective strips, gauze and bandages are applied. These dressings are changed as often as needed, the extent and depth of the burn making its own rule, usually known by the amount of drainage and odor.

The advantages of this treatment over and above that of lotions, oils or salves are: freedom from any accumulation of fats with dead epithelium, encouragement of a healthy epithelial granulation under a clean moist dressing, the Lister protective serving in the double capacity of preserving the new epithelial cells and as a temporary integument.

Finally, and not least in importance, there being almost an entire absence of fibrous tissue, there is less danger of those unsightly deformities often due to the contracting cicatrix, which is also so often accountable for the sluggish circulation and nerve pains.

#### THE TREATMENT OF SPASM OF THE LARYNX IN INFANTS.

In the *Journal de Médecine de Paris* of October 24, 1897, VARIOT speaks of the various sedative medicaments which can be employed to quiet spasm of the glottis, and suggests that in the interval between the attacks a small teaspoonful of the following potion be given three times a day:

R Bromide of potassium, 15 grains;  
Ether syrup, 6 drachms;  
Syrup of orange flowers, 6 drachms;  
Distilled water, 6 drachms.

Or the following may be employed:

R Musk, 2 grains;  
Bromide of potassium, 15 grains;  
Syrup of orange flowers,  
Distilled water, of each 6 drachms.

At night a suppository may be inserted made up as follows:

R Extract of belladonna,  $\frac{1}{4}$  grain;  
Solidified glycerin or cacao butter, 30 grains.

Night and morning it may be advisable to give the patient five drops of a mixture composed of seventy-five minims each of

aconite root and tincture of belladonna. This may be gradually increased until the patient takes twenty drops. In some cases it may be well to rub the patient's neck and chest with equal parts of lard and gray ointment. The general tendency of the treatment should be to improve the patient's nervous tone, and with this idea in view syrup of the iodide of iron or cod-liver oil are useful. Should the patient have any evidence of rachitis, and most children with spasm of the larynx suffer from this condition, remedies devoted to the relief of this state must be resorted to. Attention should also be paid to the teeth, and if the eruption of the teeth is difficult lancing should be employed. Where cases are particularly obstinate small doses of codeine, as for example one-quarter of a grain during twenty-four hours to an infant of a year, or one half to one grain during this period to a child of three years, may be given. The best way of administering it is to place the codeine in a teaspoonful of coffee. The author concludes that codeine is a valuable agent in the treatment of this condition.

[Throughout the physician should always recollect that spasm of the glottis is not a disease but the result of rickets or some perverted condition of the general system. His therapeutics should, therefore, not be devoted to the administration of nervous sedatives which will give but temporary relief, but to the improvement of the general health of the patient, the careful regulation of the diet, avoiding all substances which will produce irritation of the digestive apparatus, and the relief of the attack of croup by applying hot cloths to the throat and chest or by the use of the hot bath. Very frequently an attack may be prevented by the careful regulation of the temperature of the room in which the child sleeps, and if the air of the room is moistened by some vapor given off from slaking lime or the boiling contents of a tea-kettle, both patient and nurse may have a comfortable night by avoiding the paroxysm.—ED.]

#### PULMONARY TUBERCULOSIS TREATED BY ICHTHYOL.

In *La France Médicale* of November 12, 1897, BRANTHONNE considers the value of ichthyol in old pulmonary tuberculosis and records a number of cases in which he has employed this treatment. His method of administration is as follows: A mixture of ichthyolate of ammonium two and a half

drachms and of sixty-five-per-cent. alcohol six drachms is made, and thirty drops of this is given in a glass of water several times a day. The dose is gradually increased two drops a day until 150 drops are taken, when the ascending doses are stopped. In some cases the medicine may be given in pill form, the patient gradually going up to forty-five grains of ichthyol a day. The author of this article believes that the action of ichthyol in this case is similar to that of creosote, and quotes a number of German and French authorities who have resorted to it. The advantages of the treatment are that it does not irritate the stomach to the extent that creosote irritates it, that it diminishes the expectoration, improves the general sensations of the patient, causes an increase in weight, restores menstruation in women suffering from the disease, and altogether favorably modifies the *morale* of the patient.

#### THE TREATMENT OF ERYSIPELAS IN THE NEW-BORN BY ANTISTREPTOCOCIC SERUM.

In *La France Médicale* of November 12, 1897, DAUCHEZ insists that in grave cases of erysipelas in new-born infants the prognosis is most unfavorable, and that active treatment is needed. Under these circumstances he believes that serum therapy may be of great value. In regard to statistics concerning this matter, he quotes those of Marmorek, who had forty-five cures out of forty-six cases of erysipelas which were injected with antistreptococic serum; the forty-sixth case succumbed to an attack of pneumonia. To be sure, most of these cases were in adults. These results correspond to the conclusions of Dr. Chantemesse, who has collected statistics in regard to the results obtained by different methods of treatment of erysipelas. Thus in the classical symptomatic treatment of the disease so resorted to, out of 145 patients there were five deaths, or a mortality of 3.45 per cent.; with treatment by means of cold baths there were 409 patients with sixteen deaths, or a mortality of 3.90 per cent.—in other words, an average mortality of 3.79 per cent. On the other hand, when patients were treated by the antistreptococic serum of Marmorek, there were 297 patients with five deaths, or a mortality of 1.70 per cent., the serum being 1:7000 strength. When the weaker serum was employed—namely, 1:2000—there were 107 patients and seven deaths, or a mortality of 5.54 per cent. When the most

efficient serum was employed — namely, 1:30,000—there were ninety-seven patients and one death, or a mortality of 1.03 per cent., making an average of 2.59 per cent. These statistics demonstrate the necessity of avoiding the employment of the weaker serum.

Roger and Charrin have injected doses of five cubic centimeters into a cachectic infant of three weeks for the treatment of the erysipelas without any accident and obtained a cure in four days. The result which followed the injection of this serum was a constant, rapid and progressive lowering of the temperature. For the successful reduction of the temperature two doses of thirty cubic centimeters are usually necessary for the adult, while in children two doses of from five to ten cubic centimeters, according to age, are usually indicated. The temperature usually falls rapidly and progressively from this treatment, and the patient feels much improved. Its use also causes a diminution in the enlargement of any glands which may be swollen.

Gaucher then records the case of a male child who weighed eight pounds at birth and who at the time he came under treatment was six weeks old. He was nursed at the breast, but the mother was taken with a small abscess on the right side, furuncular in character, and the infant soon after developed suppuration about the umbilicus, which was treated by means of lotions and iodoform. Shortly after this the patient was seized with a convulsion; the rectal temperature became above normal; vomiting and finally high fever developed. No albumen, however, was found in the urine, which was passed in fair quantity. An examination at this time showed in the neighborhood of the groin on the right side a red swelling which speedily became erysipelatous in its appearance. There was also marked enlargement of the glands.

The treatment consisted in the injection of glycerin and hot bathing, and antipyrin and aconite internally. The next day the erysipelatous swelling had increased, and it continued to increase for the next week, at the end of which time the buttocks, limbs and even the feet were involved. Phlyctenular ulcers were also present. From the lower extremities the erysipelatous inflammation also extended to the trunk and shoulders. At the end of ten days the temperature was still high, the infant pallid and exceedingly feeble.

The treatment now consisted in the use of

alcoholic stimulants, coffee, ether, peptone-wine, and injections of caffeine, with the object of supporting the patient. Nourishment was maintained by giving small quantities of the maternal milk or sterilized milk every two hours.

On the fifteenth day, in the morning, it was found that the patient was exceedingly ill, the pulse was irregular, and the local treatment consisted in applying resorcin with collodion. The temperature was also very high. At this time it was proposed to commence the treatment with Marmorek's serum, and an injection of three cubic centimeters of the serum was made into the left hypochondrium. Two hours afterwards the temperature had fallen about 2°, the erysipelatous area was paler, and had not extended at all. On the next day a second injection of five cubic centimeters of the serum was resorted to, and on that night a third injection of three cubic centimeters was given. These injections did not seem to cause the infant much pain. On the following day the fourth injection of four cubic centimeters was used. The general condition had now markedly improved. The child had an excellent night, and in every way seemed much better. Three hours after the injection of the serum the temperature approached normal. The pulse became less intermittent. On the next day a fifth injection of four cubic centimeters was given, and the day following still another one was resorted to. Notwithstanding these improvements four days after the injection had been taken the patient had a turn for the worse, refused to take nourishment, and finally died. No albumen was found in the urine during the course of the attack.

The author then asks to what cause the lack of success is due in this case, and considers that the excessive violence of the disease and the extreme youthfulness of the patient, combined with the excessive temperature, are the principal factors in having brought about the fatal result.

#### THE TREATMENT OF EXCESSIVE SWEATING.

An article upon this subject is published by GAUCHER in the *Journal des Praticiens* of October 23, 1897. He states that in general hyperidrosis the best remedies in his opinion for internal administration are tannin, agaricin, phosphate of lime, and atropine. These remedies produce good results in symptomatic sweating, but they are without effect in

idiopathic hyperidrosis. In the latter condition and in symptomatic sweating, also, the administration of tonics such as iron and quinine is very useful. In nervous patients some of the antispasmodics may be employed, such as the bromide of potassium or the valerianate of ammonium, or the extract of valerian, given in continuous doses over a considerable period of time. Among the local measures which are useful we find that vinegar or alcoholic lotions, frequently repeated, or hydrotherapy with the use of cold, are the best measures of relief. In the way of astringent lotions we may employ solutions of lime, tannin, borax, or acetate of lead in any one of the following forms:

- ℞ Tannin, 15 grains;  
Alcohol, 7 ounces.
- ℞ Alum, 150 grains;  
Water, 8 ounces.
- ℞ Borax, 150 grains;  
Water, 8 ounces.
- ℞ Liquor plumbi subacetatis, 3 drachms;  
Water, 8 ounces.

Where the sweating is confined to local areas, as in sweating of the feet, foot-baths extending over a period of as long as one-half to one hour are more efficacious than lotions, and a decoction of oak bark, or oak leaves, in which is dissolved five drachms of borax in each quart, may be used as a foot-bath. After the lotions or the baths the sweating part may be dusted with the following powder:

- ℞ Finely powdered chalk, 3 ounces;  
Salicylic acid, 30 to 45 grains.

Where sweating of the feet is troublesome, it is well to separate the toes by a small piece of lint in order to prevent maceration of the cutaneous surfaces. In some obstinate cases the application of a continuous current of electricity to the part which is involved does good. In those cases of excessive sweating in which there is also a marked odor, constituting the condition known as bromidrosis, the best treatment consists in alcoholic lotions, such as we have already named, and in addition the employment of some aromatic substance; thus bathing the feet with a solution made up of five drachms of borax to the liter of alcohol, to which is added a tablespoonful of tincture of benzoin, is useful. In other cases a one- to two-per-cent. solution of potassium permanganate or a weak solution of chloride of iron may be employed. The great inconvenience of these latter two methods is that the skin is stained. In other instances a five-per-cent. alcoholic solution of

naphthol, to which has been added a minute quantity of glycerin, may be applied to the feet. After these lotions have been used the part should be powdered with a mixture of talc and salicylic acid.

#### THE ABSORPTION OF IRON AND ITS HYPODERMIC ADMINISTRATION.

LEPINE (*La Semaine Médicale*, May 26, 1897) reviews the progress of knowledge since Kobert and Bunge sought to prove in 1892 that inorganic salts of iron were not absorbed by the intestines. Kunkel has shown that after taking the inorganic salts by the mouth the percentage of iron rises in the whole body, especially in the liver. Since then iron has been repeatedly seen in microscopic sections on its way through the intestinal wall, and its eventual recovery in the feces of healthy animals has been explained. Thus Jacoby found that in animals, after hypodermic or intravenous injections of iron, very little is passed in the urine, while the greater part accumulates in the liver to be eliminated later by the intestinal mucous membrane, and probably to a less extent by the bile. Absorption from the intestine has therefore been proved. But the cases where the stomach is intolerant of iron are the very ones where it is most necessary. In these it must be given hypodermically. The latest researches show that the citrate of iron is as good as, if not superior to, any other preparation for the purpose. It appears in the urine half an hour after the injection, and is present for twenty-four hours, the maximum excretion taking place two to four hours after.

Gloevecke and others have had good results by injecting a ten-per-cent. solution into the buttocks or muscles of the back, using one cubic centimeter at a time. The injection causes a sharp pain which lasts for some time, but Lepine finds that by using more (2.5 cubic centimeters) of a weaker solution (four per cent.), this inconvenience disappears, and there is only slight tenderness. He relates a striking case of a woman, aged forty, who grew steadily worse with the usual treatment, including feeding with bone-marrow, until the hemoglobin fell to less than one-sixth of the normal, and she appeared at the point of death. Hypodermic injections of three to four cubic centimeters of the four-per-cent. solution were followed immediately by a marked improvement. Delirium ceased the day after the first injection,

and, though previously nothing was retained, four egg-flips were kept down. She had recovered a month later. In spite of the dose being in excess of that usually recommended, no bad effects were noted. There was polyuria, but no albumen. However, the common toxic symptoms produced by large doses of iron taken by the mouth, such as constipation, or sometimes diarrhea, nausea, and abdominal pain, are much more frequent after hypodermic injections. Thus a little over three grammes of the citrate when injected has produced vomiting, fever, and malaise, lasting several hours. Great caution is required if the kidneys are unsound, since even if they are healthy too concentrated injections may lead not only to the usual harmless polyuria, but to anuria and even hematuria and nephritis. The treatment is altogether contraindicated in anemic patients suffering from hepatic cirrhosis, epistaxis, hemorrhoids, metrorrhagia, etc., since it predisposes to hemorrhages. — *British Medical Journal*.

ON THE VALUE OF ARSENIC AND BELLADONNA IN THE TREATMENT OF CHOREA.

In a recent issue of the London *Lancet* OVEREND concludes an article on this topic in the following summary:

1. Belladonna appears to be most beneficial in recent cases, and its influence is sometimes very marked in severe forms.
2. In obviously rheumatic cases arsenic in large doses may be given a trial or may be combined with belladonna from the first. Belladonna may act by diminishing the excitability of the nerve centers or by imparting an improved tone to their vascular supply.
3. In the wards of a hospital it is perfectly justifiable to give to a child as much as thirty minims or more of the tincture of belladonna every four hours for ten days or even longer. Certain precautions are necessary. The patient should be kept in bed and the urine should be daily measured. Small doses of potassium acetate may be added if it becomes much diminished or if the eyelids show any puffiness. In one child nocturnal incontinence occurred, and the dose was lessened. The occurrence of the papular erythema, which leaves raised circular lumps for a time, does not necessitate any diminution of the dose. Dryness of the throat and swelling of the parotids, should they occur, are merely temporary. The in-

fluence of the belladonna makes itself felt after about four days. Should no visible improvement occur before the tenth day it would be useless to continue with it. But in eight severe cases treated belladonna was of benefit, and is certainly worthy of further trial. As soon as the movements become trivial or occur only during exertion, it is better to omit the belladonna, to commence massage of the affected muscles, and administer cod-liver oil and syrup of phosphate of iron or other tonics. The arsenic may be continued for a week or longer.

FURTHER OBSERVATIONS ON THE USE OF HYDROGEN DIOXIDE IN THE TREATMENT OF BLEPHARITIS MARGINALIS.

Dr. AYRES, the well known ophthalmologist of Cincinnati, records his experience with this substance in the *Lancet-Clinic* of October 23, 1897. Nearly four years ago the author published in the *Medical News*, of Philadelphia, a short article on the use of hydrogen dioxide in the treatment of blepharitis marginalis. He had then been using the remedy about a year in private and clinical practise, so that he can now say he has been using it constantly for five years, a period quite long enough to test its merits. His first impressions as to its value in this disease have not been disappointing; on the contrary, his expectations have been more than realized.

The author does not go into a discussion of the disease itself, but makes a few statements preliminary to what he has to say about its treatment. It is a well established fact that blepharitis is frequently associated with errors of refraction, hence it is necessary in all such cases to determine the degree of ametropia and correct it with suitable glasses. This should be the first step in every case, for two reasons: First, to relieve the asthenopia; and second, to assist by proper correcting lenses in the cure of the blepharitis. Very often there is no true asthenopia, only a burning sensation along the margin of the eyelids; but in these cases the refraction test should be made, and if even a slight error is developed it should be corrected. The correction of the ametropia will in itself help to cure the blepharitis.

Blepharitis assumes different types in different individuals. In some it is like a little dry scurf, which forms around the ciliæ and causes but slight irritation; in others there are deep ulcers around the hair-bulbs, which

are painful. Again, it is like an eczema which forms on the edges of the eyelids, causing hairy crusts, which cover half the length of the ciliae and mat them together. In the more severe types there is always more or less associated conjunctivitis. The disease is more frequently seen among the young, and especially among the strumous. In persons with fair hair and light complexion we see the most intractable cases.

If the disease be allowed to run its course unchecked there will be a gradual destruction and atrophy of the hair-bulbs from ulceration. Straggling and feeble hairs in some cases will grow out and curl down in contact with the cornea, exciting ulceration. In the inveterate cases there finally come loss of the ciliae, thickening and redness of the edge of the lids, and ectropion.

Many remedies have been used in the treatment of this disease, and with success. The mercurial ointments have long been used, and are well adapted to some, but very irritating to others. Diachylon and zinc ointments are recommended. Silver nitrate and copper sulphate are used to touch the ulcers on the lid margins, and serve a very good purpose. As this is a disease which must be treated more at home than at the office, we want a remedy which can be readily used at home and which will aid us in quickly softening and easily removing the crusts and scales from the edges of the lids. Mothers and nurses at home are entrusted with the most important part of the treatment, and they find it a difficult, and sometimes an almost impossible, task to treat the struggling and rebellious children properly. The screams of the children deter them from carrying out instructions, which they are quite willing to execute.

Water, pure or rendered alkaline by the addition of bicarbonate of soda, will in time soften the crusts, but in the hydrogen dioxide we have a remedy which, by its chemic action, unites with and softens and dissolves the crusts.

There is no need to dwell upon the great value of  $H_2O_2$  as a disinfectant and antiseptic. Every one is quite familiar with its effects on pus and micro-pus virus and albuminoids generally. It has established a wide-spread reputation for efficiency on account of its many good and few objectionable features. It is neither toxic nor corrosive, as are carbolic acid and bichloride of mercury. It acts by oxidation. It does its work quietly and painlessly. It converts pus and virus

into inert matter. It cleanses diseased surfaces as thoroughly as would the stronger preparations, and yet is as harmless as aqua pura. Its effects recommend it especially in the treatment of the eye. At first the author used it in its ordinary strength, about twelve volumes, but he soon found this objectionable, for if by accident a drop came in contact with the conjunctiva it caused a sharp pain for a short time. He then reduced it about half with water, and found this accomplished the desired result and did not pain the eye. He applies it with a bit of absorbent cotton, which is dipped into the dioxide and rubbed along the lashes. This should be kept up until the specific oxidizing effect is seen on the scales or crusts, as will be evidenced by the bubbles.

The advantage of the dioxide is that it has a softening effect on crusts along the edge of the eyelid which water does not have. Applied in the strength the writer has directed, there will soon be seen the specific action of the medicine. A white line of bubbles will be seen along the edge and the crusts will seem to swell. Keep this up for a short time and the edges of the crusts will begin to separate. Then rub the lids dry with absorbent cotton and they will become partly detached. If they should prove to be very hard and dry, the dioxide will have to be used longer, allowing it more time to soak in. Then with a dressing probe or a scoop they can be lifted out without causing pain. Water will not accomplish this so easily and so quickly, as it does not so readily unite with or dissolve them.

There is a great advantage in using this remedy in children, for it greatly lessens the pain of the treatment. After being soaked the crusts can often be brushed off with a small bit of dry absorbent cotton.

In mild cases the peroxide will give more relief than any other remedy in the author's experience. In the severe cases with ulcerations of the margins of the lids and deep pits under the scabs, the peroxide has to be supplemented by the use of a solution of silver nitrate. This is applied to the ulcers on a cotton probe made by wrapping a small bit of cotton around a wooden toothpick. It is dipped into a two-per-cent. solution of silver nitrate and then pressed into the pits until the surface turns white. This must be repeated twice a day until the ulcers fill up, and then can be discontinued.

The author frequently finds cases where ointments of all kinds produce more or less

irritation, and sometimes cause an aggravation of the symptoms. In these cases the dioxide answers very well. The writer does not claim that it is a remedy which can or should be used alone. In mild cases it will accomplish all that any other remedy can. In the severe cases the ulceration of the lid margins should be treated by nitrate of silver or other remedies. Trimming of the lashes in children should be resorted to, especially where the crusts accumulate rapidly and are not properly removed by the parents at home.

The dioxide will always be a valuable adjunct to other rational measures which are resorted to for the relief of this obstinate disease. He has also found it very valuable in the treatment of the moist eczema which forms around the *alæ nasi* and behind the ears in strumous children. It destroys the pus, softens the scabs, and renders them easy of removal.

#### *THE MODERN MANAGEMENT OF DIPH- THERIA AND CROUP CASES.*

AUGUSTUS CAILLÉ in the *Post-Graduate* for October, 1897, gives valuable advice as to the treatment of diphtheria. After stating that the proper management of the nasopharynx in children and adults is one of the most important subjects in practical medicine, he goes on to say that the nasopharynx is the usual site of entrance of diphtheria, and to this locality the preventive measures must be directed. In a contribution to the proceedings of the New York Academy of Medicine in 1884, the writer showed that chronic nasal catarrh, adenoid vegetations, enlarged tonsils and carious teeth favor diphtheria infection, and that in the absence of such conditions the instillation of a weak salt or alkaline solution into the nose morning and evening will prevent diphtheria in those exposed or prone to contract it.

The general practitioner should see to it that in all children coming under his professional care, adenoids, if present, be removed by the post-nasal forceps and Gottstein's curette, that hypertrophic tonsils be resected, and carious temporary teeth be filled or extracted.

The nasopharyngeal toilet, as advised by the author, consists in the instillation into each nostril by means of an ordinary teaspoon a spoonful of salt water one-per-cent., or boric acid water two-per-cent., morning and evening (at bedtime and on rising), as

the children lie on their backs, with nose tilted up and mouth open. The liquid does not wash through at once; some of it remains in the various recesses of the nasal cavity, and is eventually sneezed out or swallowed. In this way putrescible matter and bacteria are washed away (mechanical antiseptics). Where additional chemical antiseptic action is desired a 1:5000 mercuric bichloride solution, or Labarraque's solution ten-per-cent., or a rose-colored permanganate of potassium solution, should be employed.

The nasopharyngeal toilet, carried out in the way described, is indicated for (1) all healthy children from one year up, who live in infected localities, and (2) for all healthy children directly exposed to diphtheria infection.

It is also the best method of local treatment in all cases of diphtheria, in which instances it should be resorted to every two hours; moreover, it is the most satisfactory local routine treatment in all cases in which diphtheria frequently sets in as a complication, *e.g.*, in scarlatina, measles, and pertussis; furthermore, it is a necessity before and after tonsillotomy and all operations on the nose and throat. This method is far superior to gargling, and the writer, after an experience of more than fifteen years with its use, again takes pleasure in recommending it on account of its great value and harmlessness. It has been tested in private practise and in institutions; many physicians have employed it; bacteriologists have reported upon its usefulness, and have shown that weak solutions are as efficacious as strong ones.

In many forms of reflex cough, also of tubercular origin, it is far superior to nauseating expectorant mixtures, and in all forms of febrile disease in which the nasal secretion becomes dry, crusty, or hardened, half a teaspoonful of salt water into each nostril affords much relief.

The nasopharyngeal toilet not alone does not provoke middle-ear accessory sinus complications, but according to the experience of the writer apparently prevents them.

Specific and direct immunity is secured for those exposed to diphtheria by means of antitoxin. The period of immunity varies from three to six weeks, which is sufficient for all practical purposes in times of epidemics or house infection. Aside from the reports which come to us from abroad, we have reliable reports from various hospitals for the treatment of children's diseases throughout

the country which go to prove the absolute value of antitoxin as an immunizing agent. The immunizing dose is 200 units, and all exposed children should receive this quantity.

*Antitoxin; Dosage; Indications.*—The treatment for diphtheritic inflammation consists in the early and proper administration of reliable antitoxin, supplemented by the nasopharyngeal toilet. The time for discussing the *pros* and *cons* of antitoxin treatment is past; the specific curative power of this remedial agent is an established fact. Behring's claim that if antitoxin be used early the mortality from diphtheria will not exceed five per cent. is borne out by the reports of competent clinicians all the world over. Opposition to anything so radically new as Behring's discovery is one of the associating features in the evolution of scientific medicine. Vaccination and antiseptic surgery stand in evidence of this fact. *Any practitioner who studies the collective investigation reports for 1896 and 1897, on antitoxin for diphtheria and croup in private practise, issued by the American Pediatric Society, and fails to use antitoxin because he "does not believe in it," should not be entrusted with the management of a case of diphtheria, and the practitioner who thinks a case is mild, and waits for severe symptoms before using antitoxin, utterly fails to grasp the situation, and will frequently be disappointed.* [Italics ours.—ED.]

Antitoxin is indicated in doses of 200 units for immunizing exposed persons, and in doses of from 1000 to 2000 units to combat the disease: 1000 units for very young children; 1500 units for older children; 2000 units in croup cases. It should be employed at the earliest possible moment, and the dose repeated the following day and subsequently as often as is necessary. The author has given 10,000 units in one week to a child nine months old, and has seen no ill results. The dosage is expressed in units, and not in the serum quantity; the preparation having the highest number of units in the least quantity of serum, and from an absolutely reliable source, is to be preferred.

The injections are made in any region where a fold of skin can be picked up—the skin, the hands of the physician and the syringe must be clean. Any syringe will answer, but the best syringe is one made entirely of glass, and now obtainable in the shops.

The writer also injects a curative dose of antitoxin in every case of scarlet fever com-

ing under his notice, because this disease is frequently complicated with diphtheria, and he also administers a curative dose in case of measles and whooping-cough if the throat shows the slightest appearance of a pseudo-membranous patch. It would appear rational to give an immunizing dose in puerperal cases, where a diphtheria case exists in the same house; also to children on whom an operation is to be done in the nose or throat, and where the culture test shows the presence of diphtheria bacilli without clinical symptoms. Antitoxin is also indicated in diphtheria of the eye, which is fortunately very rare. The more common croupous conjunctivitis is not to be confounded with eye diphtheria, in which the eyelids are phlegmonous and hard.

The antitoxin rash, which is noticed in a certain number of cases, has no very characteristic features and may readily be mistaken for scarlet fever or measles rash; its appearance is usually not heralded by a rise of temperature and increase of other symptoms.

As regards the combined use of antistreptococcic and antidiphtheritic serums in cases of mixed infection, no positive advice can be formulated at the present time.

The local treatment of diphtheria must be mild. Swabbing the throat in diphtheria is harmful, and should not be practised. Solutions used as gargles do not reach the nasopharynx; the spray is only to be employed in cases in which force need not be used, *e.g.*, in docile children. The best way to cleanse the nasopharynx is to pour the liquid into the nose from a spoon; if the nose is partly or almost completely stopped up, a blunt piston syringe, or a Davidson's or fountain syringe, must be employed. In septic cases the irrigation is best done as the children lie on the side, in order to avoid any sudden strain and collapse. For the majority of cases, instillation by means of a spoon will suffice. This may be done every hour or two and if necessary day and night, according to the severity of the case. If syringes are used the stream should be directed horizontally, and not upward. Syringes should not be used if bleeding follows each irrigation.

The following liquids may be employed: Permanganate of potash (rose-colored aqueous solution); mercuric bichloride in water, 1:10,000; salt water, teaspoonful to pint; lime water; alum water, five-per-cent.; Labarraque's solution in water, 1 to 20.

Peroxide of hydrogen has shown itself to be an active irritant in the hands of the

author, and aids the spread of diphtheria, and should therefore not be used in that disease.

Any of the above liquids may be used as a gargle when children are able to gargle. Excoriations at the angles of the mouth and at the nostrils usually heal under camphor ice.

Antitoxin, with mild local treatment and judicious stimulation, will suffice for ordinary cases seen in good time; but as cases will come under observation in which valuable time has been lost in temporizing with household remedies, the physician will not be spared the management of various complications which will now engage our attention.

The local antiseptic power of a teaspoonful of medicine, as it glides over the tongue and down the esophagus, is practically *nil*. The yellow chlorate of potassium and iron mixture, and the mercuric bichloride mixture, will not be necessary where antitoxin can be had, and should under no circumstances be given to a patient with an irritable stomach. As an aid to digestion the following mixture is efficacious:

B Liquid pepsin, 2 ounces;  
Acid. muriat. dilut.,  $\frac{1}{4}$  drachm.

Teaspoonful four times a day.

In septic cases, five drops of the tincture of chloride of iron may be given every four hours.

Stimulants should be given as follows: Whiskey, American tokay wine, champagne, coffee, strychnine  $\frac{1}{4}$  grain, three times a day; camphor, one-half to one grain, three times a day; benzoate of sodium and caffeine, dose one to three grains, also subcutaneously dissolved in water; camphorated oil and ether, equal parts, five to fifteen drops subcutaneously. When the stomach is irritable, stimulating drugs can be given subcutaneously or per rectum.

High temperature can be reduced by cold and lukewarm sponge and tub baths. To give an antipyretic drug regularly every two to three hours is very bad practise; one or two doses in twenty-four hours, particularly at night, are serviceable. From three to ten grains of phenacetine with half a grain of caffeine or lactophenin with caffeine in the same dose may be given. Antipyrin is a safe antipyretic, and as it is soluble in water, from three to seven grains can be given per rectum. In cerebral unrest an ice-cap is advisable. Quinine should never be given as an antipyretic in any but malarial disease.

In cases of incessant vomiting, stop all internal medication and give only one to two drops tincture of iodine in sweetened peppermint water every hour or two, or wash out the stomach.

In many septic conditions a mild form of diarrhea may complicate matters. This can usually be checked, if necessary, by a diet of burnt flour gruel or corn-starch pap, and by omitting milk food for a time. Should this not suffice, five grains of tannic acid or tannin given with chocolate, or half a grain of acetate of lead with sugar of milk, or half a grain of camphor with one-fifth grain of Dover's powder, will check the diarrhea.

Albuminuria and nephritis are frequent complications of diphtheria. A stiff dose of calomel and jalap, and one or two warm baths a day to promote diaphoresis, will be the treatment in such conditions. In nephritis, with dropsy as a sequela of diphtheria, an infusion of digitalis may act as a diuretic by improving the circulation.

Initial convulsions indicate intense infection or nervous reflex irritability, for which an enema, a warm bath, and three grains hydrate of chloral and five grains potassium bromide are indicated, per os or per rectum. Terminal convulsions, indicating heart failure and cerebral inanition, give an unfavorable prognosis. A warm bath and stimulants are here indicated—five drops of camphorated oil and five drops of ether subcutaneously every few hours.

The tongue is sometimes so hard and dry that pain and difficulty in swallowing result. For this condition glycerin and rose water, equal parts, applied with a brush, affords relief.

Pseudo-membranous conjunctivitis is occasionally seen in severe diphtheria cases. This readily yields to ice compresses and the boric acid spray. In true diphtheria of the eye, in which the eyelids are much swollen and indurated, antitoxin must be used in large dose. Fortunately, as has already been said, this condition is very rare.

Otitis media, due to an extension of the septic process through the Eustachian tube, is frequently observed, but the earache is not nearly as intense as in ordinary otitis media, and rupture of the drumhead takes place readily. The ear should be cleansed with mercuric bichloride solution 1:5000, or a warm boric acid solution with cocaine, or menthol in sweet almond oil (one to four drachms) should be instilled.

Hemorrhage from sloughing of the tissues

is a very dangerous and distressing complication. If possible, the bleeding spot should be located by means of a strong light, and directly cauterized with the actual cautery, lunar caustic, chloride of zinc, alum solution, or antipyrin and tannin. The styptic preparations are not so applicable on account of the large grumous blood-clots which invariably form.

Phlegmon and induration of the tissues of the neck, with indistinct fluctuation of cervical lymph nodes, are best managed by a large incision through the entire dense and thick skin down to the glands. The latter are usually in a friable, spongy state, with little pus spots scattered through the tissue, and can readily be broken up by pushing a blunt director or dressing forceps through the capsule and sweeping it around in various directions in order to break up the necrotic tissue. Make one abscess cavity, which can readily be drained by means of iodoform or bichloride gauze under a moist dressing. The neighborhood of such a diphtheritic and gangrenous wound occasionally has an erysipelatous appearance, which usually subsides under the application of cold lead lotion.

The diet should consist of the following: Milk, vichy, matzoon, kumiss, beef peptonoids, corn-starch, custard, ice-water, cream, farina, cocoa, eggs, raw meat, burnt flour, soup, whiskey, California tokay, coffee, tea, punch, ice, champagne, pineapple juice, somatose.

The diet in diphtheria is of prime importance; the food should be nutritious and digestible.

Forced feeding is proper in exceptional cases, but it is well to remember that children with febrile and septic diseases have little desire for food, and that the stomach will resent all attempts at overfeeding. Somatose is an ideal soluble meat without taste or smell, and can be given with cocoa, milk, gruel, rice, etc.

For rectal alimentation inject a mixture of whiskey, egg yolk, beef peptonoids, warm water.

#### THE TREATMENT OF CARDIAC AFFECTIONS DEPENDENT UPON ARTERIO-SCLEROSIS.

In the *Journal des Praticiens* the following treatment for this condition is given:

The diet is carefully regulated and small quantities of meat are administered. In regard to vegetables, potatoes are to be avoided and green vegetables to be employed. In

regard to medicinal treatment the following potion may be employed for the purpose of increasing elimination of calcareous material: Bicarbonate of sodium  $2\frac{1}{2}$  drachms; neutralize this with a sufficient quantity of lactic acid and add lactic acid and simple syrup  $2\frac{1}{2}$  drachms, and distilled water 6 ounces. Take this quantity during a period of twenty-four hours. It is stated that the lactic acid will augment the elimination of calcareous materials and increase the quantity of the urine, and that under this treatment the patient will be relieved to a great extent of symptoms of cardiac dilatation or asthenia, his dyspnea, cyanosis, edema, and attacks of angina.

#### THE ABORTIVE TREATMENT OF INFLUENZA BY CALOMEL.

In the *Therapeutische Monatshefte* for October, 1897, FRUDENTHAL expresses the belief that calomel is an exceedingly useful drug in the early stages of an attack of influenza. The dose which he gives amounts to two grains twice a day to adults, or one grain three or four times a day. In infants smaller doses are given according to age. He asserts that the effects of this treatment are remarkable. In a few hours he obtains a great fall of temperature and the disappearance of the neuralgic pains and loss of appetite. The advantage of this treatment he thinks is that it is inoffensive, and admits of general employment. He believes that a cure can usually be produced by the third day.

#### SUCCESSFUL TREATMENT OF CIRCUMSCRIBED TRAUMATIC ANEURISM OF THE RIGHT INTERNAL CAROTID ARTERY WITHIN THE CRANIUM BY MEANS OF LIGATURE OF THE COMMON CAROTID.

HINDE (*Journal of the American Medical Association*, December 4, 1897) has reported the case of a Chinaman, thirty-six years old, who eighteen months before coming under observation had been felled to the sidewalk by a blow upon the shoulder, striking the occiput in his fall. The man at once arose and walked home, a distance of a block, and lay down for about ten minutes. On the following day he felt well enough to resume his work. Some time afterward both eyes began to redden, the right one in greater degree, and in a short time it was noticed that the right eyeball commenced to bulge forward. The redness and the exophthalmus

on the right side steadily increased until the patient came under observation, when the palpebral, conjunctival, subconjunctival and anterior ciliary veins of the right eye were found to be greatly enlarged and tortuous. No pulsation could, however, be detected in any of these vessels, and none on light palpation with the finger-tips applied to the eyeball. The motility of the globe was preserved, except that in attempts at abduction it halted at a point slightly beyond the mid-position. The reflexes of the right pupil were enfeebled. The ophthalmoscope disclosed enlargement and tortuosity of the retinal veins, but an absence of pulsation. The arteries were of normal size and course. Both arteries and veins, especially on the surface of the disk, were marked by white lines along their walls, indicative of perivasculitis. Disk, retina and choroid were normal in appearance. The veins of the left eye were somewhat enlarged throughout, but presented otherwise nothing abnormal. The sensibility of the right cornea was less acute than that of the left. The visual fields were alike and normal. The acuity of vision was slightly greater on the left than on the right, but fairly good on both sides. On placing the cup of a stethoscope over the closed right eye, a loud blowing bruit or murmur was heard synchronous with the heart beat, and an intermittence of the heart's pulsation from six to eight times per minute was readily detected. The same conditions, in slighter degree, were present over the right temporal region, and in still slighter degree in the left temporal region. In all of these situations the aneurismal sound was greatly increased when the patient stooped forward. It disappeared completely on digital compression of the right common carotid artery in the neck. On further inquiry it was learned that the patient became conscious of a noise in the head some six or seven days after his fall, and that it had grown steadily louder. The conclusion was reached that an aneurism had formed on the internal carotid artery within the cranium, perhaps secondary to fracture of one of the bones at the base, at a point where the vessel passes on the side of the body of the sphenoid bone between the layers of the dura mater and in immediate proximity to the cavernous sinus; compressing the latter and preventing the return of the venous blood from the contents of the right orbit, but not affecting the arterial supply; compressing the trunk of the sixth nerve, and in slighter degree also the

ophthalmic division of the fifth nerve. To remove the possibility of syphiloma of the brain, large doses of potassium iodide were administered for six weeks, without improvement. Operation was therefore advised, and it having been agreed to, the right common carotid artery was occluded in the neck with two ligatures, one-half inch apart. The immediate result of the operation was a complete cessation of the bruit, with increase in the exophthalmus, which, however, subsequently receded. Under treatment with the faradic current the paresis of the right external rectus muscle and diplopia that had developed were greatly improved. The ultimate result was entirely satisfactory, the patient being freed from all his previous symptoms.—*Medical Record*, Dec. 18, 1897.

---

*ON THE USE OF THE GIGLI WIRE SAW  
TO OBTAIN ACCESS TO THE BRAIN.*

According to KEEN (*Philadelphia Medical Journal*, Jan. 1, 1898) the Gigli saw has the following distinct advantages: It is simple in construction, consisting of a bit of roughened steel wire about 35 centimeters long and about 0.5 millimeters or more in diameter, with a loop at each end. Both the diameter and length vary somewhat in different sizes.

The method of using the saw is by making two or more trephine openings; then, after separating the dura from the skull, a piece of silk is passed through by means of a probe, and by the silk the saw is drawn under the skull. The handles are then attached, and by moving the saw back and forth just like the old chain saw, the skull is cut through.

In a case operated upon by the writer in sawing three sides of the osteoplastic flap, he was able at will to bevel the edge in such a way that when the flap was replaced it would not sink into the cavity of the skull and press on the brain, even though along the middle line he was obliged to gnaw away the bone at each end. By leaving one centimeter of the beveled surface in the middle, or indeed at any point, the bone is supported perfectly well. There is practically no loss of bony tissue, as the saw is so thin.

Another advantage claimed is that when the operator had completely sawed through three sides of the quadrilateral osteoplastic flap which he wished to turn down, the skull being very thick, it would have been somewhat difficult to break the bone along the fourth side, and the edges of the bone would have been very irregular and with short

spicules attached. These, if care is not taken, might prove a source of trouble to the dura when the bone was replaced. By passing the Gigli saw under the inner surface through the two openings, he was able at the base to saw half through the thickness of the skull from the inside and then break the outer table with but little exertion and a quite regular fracture.

The saw avoids the jarring of the skull caused by the hammer when the chisel is used. This is a theoretical rather than a practical advantage. The chisel has been used in a good many cases now, and no case of injury resulted from concussion of the hammer.

When one of the Gigli saws has been used it curls up and is useless. Besides this, the roughened points have been so worn away that if the skull was very thick it would probably require a second saw. One of the saws broke when the writer had been using it some little time, but all that was necessary was to withdraw the broken ends and use a new saw.

There was some anxiety while cutting the long side of the quadrilateral lest the saw, as it made the chord of an arc, the arc being the curved under surface of the skull, might cut into, or otherwise injure, the dura mater. Much gratification was felt when the flap was turned down to see that not the slightest injury had been inflicted upon the dura.

#### THE CONSERVATIVE SURGICAL TREATMENT OF UTERINE FIBROIDS.

MONTGOMERY in the *International Journal of Surgery* for January, 1898, states that hysterectomy, vaginal or abdominal, may justly be considered conservative when performed for conditions which must otherwise imperil life or health; but in this paper he uses the term in a higher sense—the conservation of function in organs which are crippled unless treated, and which have until recently been regarded as conditions justifying their sacrifice.

There are, however, many cases with extensive fibroid formations, in which by the exercise of care the growths can be removed, leaving a severely lacerated organ, which with proper management may be restored to a functioning organ capable of affording hope for, if not actual, future progeny.

The growths may be attacked either through the vagina or by way of the abdomen.

The truly conservative procedures *per vaginam* are:

1. Dilatation and curettement of the uterine canal.
2. Splitting of the cervix.
3. Incision of the tumor capsule.
4. Removal of the tumor after twisting or cutting its pedicle.
5. Arrest of blood-supply by ligation of vessels.
6. Enucleation.
7. Morcellation.

The first three procedures, unless a part of a general plan, are merely palliative. Dilatation of the cervix by laminaria tents affords an opportunity for digital exploration of the cavity and the determination of the size, situation and relation of intramural and interstitial growths. By decreasing the resistance of the cervix it promotes the more rapid extrusion of the tumor. The same effect to a more marked degree is accomplished by splitting the cervix. This is not applicable for a tentative procedure, unless the growth is already making pressure upon, and has partially taken up, the uterine neck.

The influence of curettement is confined to its palliative effect in the arrest of hemorrhage. For this purpose it is especially valuable, and produces such changes in the diseased uterine mucosa that hemorrhage may be kept in abeyance for a considerable period. It should not be employed when the tumor is a polypus, merely attached by a pedicle. Such cases should be treated by division of the pedicle through torsion or incision and delivery of the growth. This plan of treatment is preferable whenever the pedunculated growth can be reached after dilatation or splitting of the cervix. The growth should be seized by strong, preferably four-pronged, vulsella, and rotated two or three times until its pedicle is torn off, when the delivery can be accomplished by traction. The latter should not be employed until it is certain the pedicle is loosened, otherwise inversion might readily be produced.

Incision of the tumor capsule and partial enucleation of the growth is of particular advantage in controlling hemorrhage. The divided vessels retract and become occluded by clots.

It facilitates the extrusion and conversion of interstitial or mural growths into the intramural. The resistance of the tissue intervening between the growth and the uterine cavity is withdrawn, and in some cases the extrusion is rapid.

It is not absolutely free from danger; the premature removal of resistance may cause so rapid extrusion that the blood-supply is arrested, and it becomes a sloughing fibroid, greatly increasing the danger to the patient.

Cutting off the blood-supply by ligation of the uterine arteries was advocated in 1890 and first performed by Martin in 1892. As done by Martin, it is not only a ligation of the uterine arteries, but the whole base of the broad ligament is secured in order to occlude not only the main channel of the uterine artery, but its collateral branches. In very vascular growths, he also burrows up and secures the ovarian artery upon one side. Naturally the best criterion of the value of any procedure is determined by practical experience. In thirteen cases reported by Martin, upon whom the operation had been done more than a year, the tumor entirely disappeared in several; in others it decreased in size; while in three the hemorrhage was but slightly improved.

The advantages of the procedure are that it can be done without opening the peritoneal cavity and thus subjecting the patient to a dangerous operation. The absence of an external incision and the slight peril of the operation render it more acceptable to the patient.

Among the disadvantages are: the possibility of ligating or injuring the ureter; the difficulty sometimes experienced in reaching the uterine arteries; the possibility of securing so effective an arrest of blood-supply that the tumor, incompletely nourished, undergoes caries or necrosis, when the danger is greatly enhanced.

The complete absorption of a mature fibroid, or one which encroaches largely upon the uterine cavity, must be doubtful. The retention of a portion of such a growth must be a menace, should the patient become pregnant, as it may be a source of dystocia and the increased nutrition lead to its development. The influence of the reduced supply of blood to the uterus upon the subsequent possibility of conception and ability of the organ to nourish the product to full term is worthy of consideration.

Enucleation of growths which have been pushed into the uterus, forming sessile tumors, when the uterine canal has been partially or completely dilated, has long been practised. When the tumors were of considerable size it has been supplemented by removal piecemeal or morcellation.

What the author particularly wishes to

impress is that by a combination of these methods we may succeed in removing growths, and leave a functioning uterus in cases where it has formerly been deemed necessary to sacrifice the organ.

Sessile, and particularly interstitial, growths situated in the body of the uterus, with a long undilated cervix, have been regarded as either requiring long-continued medical treatment or the sacrifice of the body of the uterus. The former means months or even years of invalidism before the tumor can be so extruded as to render it readily accessible; the latter, the sacrifice of the fondest hopes and the highest aspirations of a woman's life. If such a growth is found in woman near the climacteric, that plan of treatment should be employed which affords relief with the least discomfort and danger; but in a young woman the retention of function justifies greater risk. The procedure the writer suggests is a combination of the various methods already discussed:

First, efficient dilatation of the uterus to at least permit the exploration of its entire cavity with the finger. This dilatation may be accomplished with the repeated use of laminaria tents, or Vulliet's method with gauze packing. With either procedure, the vagina should be rendered as nearly sterile as possible. This is best accomplished by exposing the cervix with retractors, and cleansing the vagina and cervix by repeated swabbing with a formalin solution (1 to 1000); hollow laminaria tents which have been soaked in a saturated solution of iodoform in ether are introduced, or a number of small ones. They are kept in place by a tampon of iodoform gauze. The tents may remain from twelve to twenty-four hours. Unless the cervical canal is very narrow, the dilatation secured by one set of tents will be sufficient for the purpose of the investigation. If it cannot be satisfactorily accomplished, the canal should again be filled with tents, previously taking the precaution to cleanse the vagina and irrigate the uterus with the formalin solution. If the operator is unprepared to proceed to removal of the mass, the dilatation may be retained by packing the uterus firmly with iodoform gauze.

The next procedure will depend upon the size, situation and accessibility of the growth. If well within the cavity, it can be rendered more accessible by splitting the cervix up to or even beyond the internal os. The portion incised will depend upon the situation of the growth. Near the fundus or in a lateral wall

it will probably be more readily exposed by lateral incisions. The anterior and posterior lips are each seized with a double tenaculum and drawn apart while the lateral incisions are made with a bistoury. Care must be exercised not to injure the ureters, which will probably be caused to approach the cervix by the wide eversion of the lips. The incisions do not enter the peritoneal cavity, but permit the uterus to be drawn into the everted broad ligaments as the incision may be carried into the lateral fornices, always keeping in mind the proximity of the ureters. Bleeding from the circular artery or other branches of the uterine artery is temporarily controlled by hemostatic forceps.

In sessile or mural growths of the anterior or posterior wall, not unfrequently the tumor may be more readily exposed through an anterior incision. The dissection of the bladder from the uterus will permit of an extensive exposure. Having made the incision the margins of the wound should be retracted by sutures of heavy silk, as less likely to injure the walls than the double tenacula. Upon exposure the capsule of the tumor should be incised. In mural growths this incision may bifurcate laterally, permitting the overlying uterine tissue to be dissected in two flaps. A firm grasp of the exposed tumor is made, and it is drawn upon while the tissues are pushed off with a blunt dissector, so curved at its end that it will closely hug the surface of the tumor. Such an instrument is preferable to the finger for dissection, as it occupies less space, will do less injury, and is not so likely to carry infection. If the tumor is too large to permit of its complete enucleation, it can be reduced by morcellation. As enucleation progresses it may be facilitated by rotation of the tumor, thus twisting it out of its bed. After the removal of the tumor the parts should be thoroughly irrigated, the torn mucous membrane adjusted, and the cavity packed with a long strip of iodoform gauze, the end of which projects from the cervix. The incised surfaces are accurately brought together with sutures, exercising care that the sutures do not include the protruding gauze. After closure of the incision in front of the uterus, the peritoneal and vaginal surfaces should be sutured to it, placing a gauze drain through the latter.

If the lateral fornices of the vagina have been opened and the cellular tissue much disturbed, a gauze drain should be inserted on each side. The gauze drains should be

removed between the third and fifth day, according to the patient's progress. For the ready accomplishment of this operation through the vagina, the uterus must be movable, the tumor not larger than the fist, and the vagina moderately dilated or dilatable.

Where the conditions are unfavorable the growth must be attacked through an abdominal incision. The conservative abdominal procedures are: Ligation of ovarian arteries; myomectomy; enucleation.

The arrest of blood-supply by ligation of the ovarian arteries and anastomosis of ovarian and uterine arteries, as advocated by Robinson, has been demonstrated as capable of reducing the size of fibroid growths, but is open to some of the objections brought against vaginal ligation. A serious operation has been performed which is not certain to produce a favorable result. The tumor remains to undergo degenerative processes or take on new life and development.

Myomectomy has long been recognized as a proper procedure in the treatment of pedunculated extramural growths.

Enucleation of fibroid growths through the peritoneum has been exceptionally practised. Kelly recently read a paper advocating it before the American Medical Association. Chevrier in 1892 reported one hundred and twenty-five cases thus treated with a mortality of sixteen per cent. He cautions against opening the uterine cavity. Is there any reason why the operator should fear to follow it, if necessary, even into the uterine cavity? The wound in the remaining portion of the uterus can be readily sutured, and with just as reasonable hope of success as in the suture of the incision of a Cæsarian section.

In young women, then, we would advocate the enucleation of fibroid growths, even so large as to require the abdomen to be opened, whenever the condition of the ovaries and tubes presents no barrier to the hope for complete restoration of the functions of the pelvic organs. The capsule of the tumor should be incised and the enucleation accomplished with the use of the metal dissector; bleeding vessels should be secured with hemostats, and where the uterus is occupied by a number of growths, the cavity should be temporarily packed with gauze held in place by a suture, otherwise it may become lost in the abdomen and be overlooked. Mural or even intramural tumors should not be considered as contraindicating this method of procedure. In such cases, however, it may

be a question as to the wisdom of drainage by gauze through the vagina. Such practise would necessitate previous sterilization of the vagina. After the enucleation of the growths the cavity should be carefully dried, where the uterine cavity has been entered, the mucous surfaces adjusted and the walls apposed, using for this purpose sterilized catgut.

*A NEW INCISION FOR ARTHRECTOMY, RESECTION, AND FOR REDUCTION OF IRREDUCIBLE DISLOCATION OF THE SHOULDER-JOINT.*

In the initial number of the *Philadelphia Medical Journal* SENN brings forward the incision for arthrectomy given below. The modern operations for tuberculosis of joints requiring arthrectomy or resection are characterized by thorough removal of the diseased tissue through incisions which afford free access to the joint, and that do not inflict unnecessary damage to important muscles, vessels, and nerves. The ultimate success of such operations depends largely upon the thoroughness with which they are performed, the care exercised in the preservation of healthy tissue, and the prevention of injury to important structures involved at the site of operation. The incisions which are being devised for resection of the different joints have these two objects in view, and the recent improvements in the surgery of joints are largely due to a more perfect technique in performing the operations. The success that has attended the open method in the reduction of irreducible dislocations has added a new impulse to this department of surgery. Attempts to reduce old dislocations of the shoulder-joint have, in the hands of the most careful and competent surgeons, frequently terminated in disaster, so that the surgeon of to-day has learned caution, and is more inclined to remove the obstacles to reduction by a safe and clean dissection than by brute force.

The object of this paper is to describe a new incision for exposing the shoulder-joint for different indications. Senn then gives a retrospective view of the different incisions which have been devised from the time the first excision of the shoulder-joint was made until the present. The incision that he has devised has the great advantage over Bardenheuer's that the scar resulting from the operation is well protected by the prominence formed by the shoulder-joint, and at the same time secures free access to every part of the

shoulder-joint and its immediate vicinity. The external incision is made so as to form an oval cutaneous flap, which is turned upward, exposing the upper half of the deltoid muscle. It is commenced over the coracoid process, and is carried downward and outward in a gentle curve as far as the middle of the deltoid muscle, when it is continued in a similar curve upward and backward as far as the posterior border of the axillary space on the same level where it was commenced—that is, a point opposite the coracoid. The semilunar flap is dissected up as far as the base of the acromion process and reflected. The acromion process is detached with a saw and turned downward, with the deltoid muscle attached. The capsule of the joint is now freely exposed.

If the operation is performed for an irreducible dislocation of the shoulder-joint, the head of the humerus can now be located; the cause of resistance to reduction is sought for and removed, or corrected when the reduction can be accomplished by direct means, or by direct measures and manipulation. If the operation has for its object the removal of diseased tissue, the capsule is opened and the interior of the joint subjected to a careful examination, to determine the extent of the operation. If the disease is limited to the soft structures a complete arthrectomy can be performed without sacrificing any portion of the bony constituents of the joint by dislocating the head of the humerus in different directions for the purpose of rendering the entire capsule accessible to the dissecting forceps, knife, and scissors. If the head of the humerus is sufficiently diseased to indicate a typical resection, it should be removed as a preliminary step to the subsequent arthrectomy. The glenoid cavity is readily accessible, and should be dealt with in accordance with the pathologic conditions present. After the removal of all diseased tissue, and proper preparation of the wound, the acromion process is replaced and held in position by two or three strong catgut sutures. Silver wire is seldom required in suturing a temporarily detached bony prominence in operations upon the different joints. The catgut sutures hold the fragment long enough in place for bony union to occur. Senn very rarely drills the bone-ends, as the sutures gain a sufficiently strong hold by including the periosteum and the paraperiosteal structures. In operating upon the shoulder-joint for disease, through-tubular or capillary drainage should be es-

it will probably be more readily exposed by lateral incisions. The anterior and posterior lips are each seized with a double tenaculum and drawn apart while the lateral incisions are made with a bistoury. Care must be exercised not to injure the ureters, which will probably be caused to approach the cervix by the wide eversion of the lips. The incisions do not enter the peritoneal cavity, but permit the uterus to be drawn into the everted broad ligaments as the incision may be carried into the lateral fornices, always keeping in mind the proximity of the ureters. Bleeding from the circular artery or other branches of the uterine artery is temporarily controlled by hemostatic forceps.

In sessile or mural growths of the anterior or posterior wall, not unfrequently the tumor may be more readily exposed through an anterior incision. The dissection of the bladder from the uterus will permit of an extensive exposure. Having made the incision the margins of the wound should be retracted by sutures of heavy silk, as less likely to injure the walls than the double tenacula. Upon exposure the capsule of the tumor should be incised. In mural growths this incision may bifurcate laterally, permitting the overlying uterine tissue to be dissected in two flaps. A firm grasp of the exposed tumor is made, and it is drawn upon while the tissues are pushed off with a blunt dissector, so curved at its end that it will closely hug the surface of the tumor. Such an instrument is preferable to the finger for dissection, as it occupies less space, will do less injury, and is not so likely to carry infection. If the tumor is too large to permit of its complete enucleation, it can be reduced by morcellation. As enucleation progresses it may be facilitated by rotation of the tumor, thus twisting it out of its bed. After the removal of the tumor the parts should be thoroughly irrigated, the torn mucous membrane adjusted, and the cavity packed with a long strip of iodoform gauze, the end of which projects from the cervix. The incised surfaces are accurately brought together with sutures, exercising care that the sutures do not include the protruding gauze. After closure of the incision in front of the uterus, the peritoneal and vaginal surfaces should be sutured to it, placing a gauze drain through the latter.

If the lateral fornices of the vagina have been opened and the cellular tissue much disturbed, a gauze drain should be inserted on each side. The gauze drains should be

removed between the third and fifth day, according to the patient's progress. For the ready accomplishment of this operation through the vagina, the uterus must be movable, the tumor not larger than the fist, and the vagina moderately dilated or dilatable.

Where the conditions are unfavorable the growth must be attacked through an abdominal incision. The conservative abdominal procedures are: Ligation of ovarian arteries; myomectomy; enucleation.

The arrest of blood-supply by ligation of the ovarian arteries and anastomosis of ovarian and uterine arteries, as advocated by Robinson, has been demonstrated as capable of reducing the size of fibroid growths, but is open to some of the objections brought against vaginal ligation. It is commenced over the coracoid process, and is carried downward and outward in a gentle curve as far as the middle of the deltoid muscle, when it is continued in a similar curve upward and backward as far as the posterior border of the axillary space on the same level where it was commenced—that is, a point opposite the coracoid. The semilunar flap is dissected up as far as the base of the acromion process and reflected. The acromion process is detached with a saw and turned downward, with the deltoid muscle attached. The capsule of the joint is now freely exposed.

If the operation is performed for an irreducible dislocation of the shoulder-joint, the head of the humerus can now be located; the cause of resistance to reduction is sought for and removed, or corrected when the reduction can be accomplished by direct means, or by direct measures and manipulation. If the operation has for its object the removal of diseased tissue, the capsule is opened and the interior of the joint subjected to a careful examination, to determine the extent of the operation. If the disease is limited to the soft structures a complete arthrectomy can be performed without sacrificing any portion of the bony constituents of the joint by dislocating the head of the humerus in different directions for the purpose of rendering the entire capsule accessible to the dissecting forceps, knife, and scissors. If the head of the humerus is sufficiently diseased to indicate a typical resection, it should be removed as a preliminary step to the subsequent arthrectomy. The glenoid cavity is readily accessible, and should be dealt with in accordance with the pathologic conditions present. After the removal of all diseased tissue, and proper preparation of the wound, the acromion process is replaced and held in position by two or three strong catgut sutures. Silver wire is seldom required in suturing a temporarily detached bony prominence in operations upon the different joints. The catgut sutures hold the fragment long enough in place for bony union to occur. Senn very rarely drills the bone-ends, as the sutures gain a sufficiently strong hold by including the periosteum and the paraperiosteal structures. In operating upon the shoulder-joint for disease, through-tubular or capillary drainage should be es-

established and continued for two or three days. The divided portion of the deltoid muscle is sutured separately with catgut, when the cutaneous flap is brought down in position and sutured in the usual manner.

In operations for irreducible dislocation drainage is not required, and primary healing of the deep and superficial wounds should be aimed at by careful suturing. After applying a copious hygroscopic aseptic dressing, the arm should be immobilized against the side of the chest with a few turns of the plaster-of Paris bandage. The operation as described, undertaken for the reduction of an irreducible dislocation, arthrectomy or resection for disease of the joint, does not involve any of the important tendons, muscles, vessels, or nerves, and for this reason a good functional result may be confidently expected.

---

*A CASE OF STRANGULATION OF THE ILEUM BY PASSAGE THROUGH A CONGENITAL MESENTERIC HOLE; OPERATION; RECOVERY.*

J. STANLEY KELLETT SMITH reports a case under this heading in *The Lancet* of October 30, 1897. It is as follows:

A girl, aged fifteen years, was seized, while walking in the street on the afternoon of June 23, 1897, with violent abdominal pains, quickly followed by persistent vomiting. Mr. Bassett Jones, of Aberystwith, who saw the girl the next morning, reported on her condition then as follows: "The patient complained of severe pain referred to the umbilical region; the pain was continuous, but accompanied with paroxysmal exacerbations about every ten minutes, during which the patient suffered great agony. The tongue was furred. The pulse was 90, sharp and small; the respirations were 20; and the temperature was 98.2° F. The abdomen was flaccid and flat, with the walls moving on respiration; there was no local swelling to be seen. It was resonant on percussion, but not tympanitic; there was a small area of dulness in the right iliac fossa, over which there was some tenderness on pressure. Palpation revealed nothing except a sense of resistance over the above mentioned area of dulness. There was no passage of flatus or feces. Vomiting was frequent and of a bilious character; the act was preceded by much nausea, and the stomach emptied itself without much apparent effort. Rectal examination revealed only the presence of small

scybalæ." The lower bowel was emptied by enemata and everything that could be suggested in the way of palliative treatment was tried, but without relief to the symptoms.

The author saw the patient in consultation on June 27, four days after the onset of the illness. Intestinal obstruction had remained complete, and she was then in a state of great exhaustion. The pulse was 140 and of very unpromising character; the respirations were 32. The abdomen was tympanitic, except a small patch of dulness in the right iliac region, and over this patch any pressure upon palpation was strongly resented by the muscles of the abdominal wall. When he saw her vomiting had just taken place, the ejected matter consisting of diluted bile with particles of curd of the milk which had been given in small quantity as food. There was no suspicion of fecal odor.

Operation was advised and immediately carried out. The abdomen was opened from the umbilicus to the pubes. Coils of distended and congested small intestine bulged through the wound, and the escape of these was encouraged until the disposition of the mesentery could be comfortably made out. The gut was then carefully drawn from the abdominal cavity, proceeding always downwards, until the lower part of the ileum was reached, tender manipulation being here necessary owing to the greatly increased congestion of the bowel. The cause of the mischief was found in the shape of a hole in the lower part of the mesentery, pyriform in shape, measuring some two and one-half inches by two inches, with its larger end close to the mesenteric attachment of a small loop of bowel, which, taking its upper and lower limits as fixed points, had swung itself through the hole and thus become strangulated. The parts were judged capable of recovery and so were restored to normal position, recurrence of the accident being guarded against by closure of the aperture. The exposed intestines were then washed with weak perchloride solution and replaced in the abdominal cavity with some difficulty but without the necessity of puncture for gas drainage. The total time of operation occupied thirty-five minutes. Recovery was uninterrupted. Flatus passed on the day following the operation, and the bowels were voluntarily moved on the fourth and subsequent days.

Holes may occur in the mesentery as the result of disease, of injury, or of congenital malformation. The absence of any sign of

previous disease or injury and the negative history thereof, the smooth, thickened margin of the aperture, its size and the regularity of its outline, and especially its situation in the lower part of the mesentery, at the spot where such developmental deficiencies most frequently occur, lead the author to regard this case as a typical example of a congenital mesenteric foramen.

#### SECRETION NEUROSIS OF THE COLON.

In *Mathews' Quarterly Journal of Rectal and Gastro-Intestinal Diseases* for January, 1898, BYRON ROBINSON discusses this subject and reaches the following results:

1. The above disease of the colon should be termed secretion neurosis and enteritis. The first is of neurotic origin and course.
2. Both secretion neurosis and enteritis may coexist.
3. Secretion neurosis of the colon occurs chiefly in neurotic females (eighty per cent.).
4. It is closely associated with genital disease.
5. It is frequently preceded by constipation (a neurosis of the fecal reservoir or of the inferior mesenteric ganglion).
6. The continuation of the disease is partly due to an irritable, vicious habit of excessive epithelial activity.
7. The disease is characterized by colicky pains, with the evacuation of mucous masses.
8. It is not fatal, variable and erratic in attacks, with impossible prognosis as to time.
9. Microscopically the evacuations appear as membranous, yellowish-white masses of mucus.
10. Microscopically one sees hyaline bodies, cylindrical epithelium, cholesterine crystals, triple phosphates, round cells, various kinds of micro-organisms, and pigment.
11. Chemically the evacuations consist of mucin and albuminous substance.
12. Secretion neurosis of the colon is comparable to the secretion neurosis of the endometrium (membranous dysmenorrhea) or bronchial croup.
13. Secretion neurosis of the colon appears to be limited chiefly to the part of the colon supplied by the inferior mesenteric ganglion—i.e., to the fecal reservoir (the left half of the transverse colon, the descending colon, the sigmoid, and rectum).
14. It is a disease of the sympathetic secretory nerves, and is analogous to the disease of the motor and sensory nerves of the viscera.

15. Its treatment consists in removing the neurosis, which lies in the front ground, and regulating the secretion, which lies in the background.

16. Three views exist as to the above disease, which certainly embrace more than one pathologic process, viz.: (a) That the disease is enteritis (catarrh); (b) that it is simply excessive secretion of mucus (colica mucosa); (c) that it is a secretion neurosis of the colon (nervous).

#### THE APPLICATION OF HOT WATER IN SURGERY.

BOYCE (*Atlantic Medical Weekly*, Jan. 1, 1898) in an interesting contribution to this subject reminds us that a good deal of ingenuity and research has been expended in devising, for laboratory use, a normal salt solution—that is, an exact chemical solution in which each cell shall have its greatest physiological activity. It is a little surprising that the advanced surgeon, ready enough to avail himself of laboratory work in most other directions, has as yet done nothing in this. Its importance may be in some degree appreciated by those who have followed Schleich's study of the varying effects which follow from slight differences in the saline density of solutions used in inducing anesthesia by the infiltration method. The abdominal surgeons long ago learned that the best method of securing asepsis was not by indiscriminate poisoning, but by securing for the vital elements of the peritoneum the fairest possible field in their contest with bacteria and bacterial products. But when other tissues are concerned we are apt to forget that they are not mere dead surfaces, nor do we always deal with them with a full appreciation of their biological properties.

These considerations are, however, of merely speculative interest until they shall have been thoroughly worked out for us and given a clinical application by men whose perfect command of present methods has given them the right to experiment. For the present those of us who are called on in emergency will content ourselves with approximation to a normal salt solution as is furnished by a six-tenths per cent. solution of sodium chloride. A teaspoonful of ordinary table salt is always within reach; dissolved in a quart of hot water it forms a solution safe even for intravenous injections.

Premising, then, that the water shall be freshly boiled and of such a saline density as

is most acceptable to the tissues, let us inquire what are its physiological effects. One hundred and ten degrees Fahrenheit is about the maximum temperature at which the whole body can be immersed with comfort, but when heat is to be applied to a limited portion of the skin higher temperatures can be borne. Thus, while 120° F. would perhaps be the limit for the immersion of the hand or foot, 140° F. is not particularly painful when applied to a limited area. At 150° F. the pain becomes quite severe and the erythema produced is of several minutes' duration. There is, however, no blistering, nor evidence of inflammatory reaction. It is a matter of common observation that the deeper tissues of the wound are less sensitive, and will bear a higher temperature than the skin edges. At 159° F. coagulation of proteids and consequent destruction of vital activity is produced.

The effect of the application of these high temperatures varies greatly according to the length of the exposure. At first the vessels are entirely relaxed; the part is congested, red, swollen, and soggy; its superficial veins are distended and tortuous, its lymph spaces filled with fluid. In a short time, however, this picture is changed. The part becomes pale, dry, and shriveled, drained of fluid, both in blood-vessels and lymph space. This reduction of congestion, seen in pathological conditions as well as normal, is perhaps the most important surgical application of moist heat. The gynecologist makes most extensive use of it with his treatment of turgid pelvic viscera by prolonged hot douching.

Quite lately there has been introduced a treatment for gonorrhea by prolonged irrigation of the urethra with very hot water. The fact that a very small quantity of permanganate of potassium is dissolved in the water probably contributes but little to the success of this method of treatment.

A class of cases in which the value of the hot application has been overlooked is the very common one of joint sprains, particularly those of the ankle. A sprained part immersed in water heated up to the limit of endurance at first throbs and burns most painfully, but soon, in twenty minutes to an hour, its swelling and tenderness lessen, the part becomes more movable, and comfort is restored. The dependent position rendered necessary for immersion is a disadvantage; in the intervals of application the part should be elevated.

This method of treatment of a sprain will

probably never attain great popularity, for it cannot afford such instantaneous relief of pain and disability as does the method by strapping. The delight and gratitude of a patient whose sprained ankle has been properly compressed and supported is something not easy for a physician to forego, yet the author believes that the immediate relief is at the expense of the ultimate strength of the part, and that if the profession would adopt a different line of treatment, we would hear less of ankles not to be depended upon for walking on level ground and of shoulder-joints that go out on slightest provocation.

Another use of continued hot applications, in promoting suppurative processes, is now more honored in the breach than in the observance. With the passing away of the "laudable" character of pus, has passed also all our laudation for the poultice. Yet the septic character which was incidental to the old-fashioned poultice should not blind us to the value of its essential elements—heat and moisture. The same effects are today secured by continued immersion in cases where large sloughs are to be separated. This method prevents obvious inconveniences which restrict its application to the more serious cases. A moist dressing, consisting of antiseptic gauze applied dripping out of very hot water, covered with a heavy layer of flannel to retain heat, and this again with oiled muslin or rubber tissue to retain moisture, constitutes a clean poultice of great value in many minor cases. The author refers to such cases as abscess, cellulitis, lacerated wounds, etc., infected when we first see them, where, in spite of free incision, and with no apparent mechanical obstruction, drainage is yet not free when the tissues about the wound are swollen, infiltrated, red, and painful. One application of a dressing such as described above will do more for such a case than days of antiseptic cleansing.

Next we come to the use of hot water as a hemostatic. For this purpose it is applied at a sufficiently high temperature to clot the blood in the vessels back to their trunks, and to cover the wound with a peculiar dry glaze. This effect is extremely useful in drying up the field of operation, allowing us to distinguish one tissue from another where a moment before was one uniform surface, red and oozing.

An extended series of cases where the tip of the finger had been sliced off with a sharp knife, leaving the exquisitely tender pulp exposed in the wound and spouting

blood, enabled the author to demonstrate the superiority of hot water to other agents, such as acetanilid, peroxide of hydrogen, alum, etc., which are said to control capillary hemorrhage without interfering with healing; and the application of heat in this manner seemed to promote in no small degree aseptic healing, which in this case was by scabbing. So manifest was this effect as to suggest the possibility of sterilizing wounds by moist heat.

We know that the ordinary pyogenic bacteria are not extremely tenacious of life, that they are destroyed, when moist, at a temperature not much above 140° F., while the tissues will stand without disintegration a temperature of 150° or more. So it seems probable that by the application of such a degree of heat as is within the limits of safety we may at least exert an inhibiting effect on the activity of the pyogenic organisms sufficient to give the tissues the advantage in that struggle upon which clinical asepsis always depends.

#### TREATMENT OF COLLES' FRACTURE.

EDWARD A. TRACY (*Journal of the American Medical Association*, Nov. 20, 1897), speaking on the subject of the treatment of Colles' fracture, says that since the recognition by Colles of the real nature of this injury, there had been a marked tendency till within recent years to overtreat it, with more or less baneful results. Sir Astley Cooper advised that four or five weeks be let elapse before passive motion in the aged be attempted. He remarked that recovery is slow, it sometimes being six months before the finger motions were restored. Agnew, Bryant, Moullin, Walshe and McClelland all recognize that the stiffness of the fingers and wrist is due to the fibrinous exudations around the tendon sheaths about the seat of the fracture. Bryant states that passive movements ought to be employed by the surgeon at an earlier period than has been wont; but that time he does not specify.

Moullin advises passive motion of the fingers from the first day, stating that this generally prevents stiffness of them. With the wrist, he states, it is generally more difficult (to prevent stiffness), "but on several occasions the author has begun gentle manipulations on the fourth or fifth day with excellent results." Tracy believes that Moullin's very definite instruction in regard to passive movements of the fingers to be begun at once, and of the wrist-joint on the

fourth or fifth day, is good practise, and that it ought to become general. All surgeons probably will agree with Roberts ("Fracture of the Radius," Philadelphia, 1897) that "the displacement (in Colles' fracture) is the result, not of muscular action but of the vulnerating force," and further, that "the muscular surroundings have little to do with the causation or continuance of the distortion." For this reason the fracture, if reduced, has no tendency to again separate. It would seem, therefore, that all that is needful after reduction of the fracture is some simple appliance that will protect the parts from accident while reuniting, and that will not interfere with passive motion of the fingers from the first day. Swinburne's practise of many years ago, referred to above, was good, though his explanation of it, by the principle of extension applied to the parts, was faulty. The author in several cases, after reduction, has molded a piece of wood-fiber splint material over the dorsum of the forearm and hand in a semiprone position, the hand in line with the forearm. This, bandaged over the parts, he finds sufficient protection for them. It does not interfere with passive motion of the fingers, and is readily removed and reapplied to permit of passive motion of the wrist-joint. It is molded directly over the skin, and requires no padding or compress. In these cases he has carefully caused passive motion of the wrist-joint from the fifth day, and discarded the splint on an average of about twenty-one days.

The author believes that the treatment of Colles' fracture could thus be formulated: (1) Reduction, not always easy; (2) protection by a simple retentive appliance while correct reunion of the bone takes place; (3) passive motion of the fingers from the first day; of the wrist, carefully, from the fifth day.

#### THE TREATMENT OF COXALGIA.

JALAQUIER (*La Presse Médicale*, June 26, 1897) is opposed to resection, and thinks this operation should be reserved for coxalgias complicated with constantly discharging fistulas or abscesses that have resisted punctures followed with injections of camphorated naphthol or of iodoform ether. The operations of the author have been atypical, and he never has felt sure that he has arrived at an entire curettage of the articulation. He agrees with Menard that preliminary injections create a condition favorable to the suc-

cess of the operation. In the treatment of non-suppurative coxalgias he is not exclusive. In the hospital and where the patient can be closely watched he employs continued extension. When the case cannot be attentively watched, Dr. Jalaquier applies the plaster at first after resection under chloroform, if the position is defective. He agrees with Brun in saying that abscesses do not follow more frequently in children treated by this method than in those treated by continued extension.

The author does not share the fears expressed by Kirrison relative to resecting under chloroform a coxalgia in defective position with or without dislocation, but he emphasizes the statement that he does not employ this method in coxalgias complicated with abscess. When coxalgias are cured or almost cured in a defective position, subtrochanteric osteotomy gives good results. Of one hundred and twenty-two cases treated at the Trousseau Hospital, sixty-seven have presented abscesses. Of the one hundred and twenty-two cases eleven died—seven of meningitis, four of pulmonary complications. This mortality rate is not accurate, as many of the children were not watched to the end. Of the one hundred and twenty-two cases forty-six were treated by simple continued extension, and it is curious that in this series we find five deaths from meningitis and four from pulmonary complications. Eighteen were treated by simple immobilization without resetting; they furnished two deaths from meningitis. Forty-one patients submitted to resecting under chloroform. In this series he found no deaths from meningitis or pulmonary complications. This may be due to good fortune, but the author thinks it is because he has never applied forced resection in children having abscesses or when the general condition was bad.

As to the comparative value of camphorated naphthol and iodoform ether in the treatment of abscess, the author states that sixteen abscesses were cured after sixty-eight injections of camphorated naphthol, or an average of three or four punctures for each patient. Twenty-three abscesses were cured after fifty-two injections of iodoform ether, or about two punctures for each patient. Twenty-two abscesses were cured by the combination of the two agents. Abscesses that proved refractory under camphorated naphthol were cured after several injections of iodoform ether. Some abscesses thus treated became fistulous, but the proportion

cannot be exactly given; this occurred only when the skin was ready to break spontaneously. The cure of these fistulas can be obtained if care is taken to avoid secondary infection and resort is had to frequent touchings with a solution of lactic acid, one in three.—*Medical Record*, Oct. 30, 1897.

#### THE TREATMENT OF THE PAINS OF ATAXIA BY METHYLENE BLUE.

It is stated in the *Journal des Praticiens* that LEMOINE has found this substance of value for the relief of ataxic pains. In two cases he failed to obtain good results from its use, but in five out of seven others there was a great diminution in the intensity and frequency of the pains, the relief being complete and prolonged. The pains which seem to be best relieved by methylene blue are the darting pains in the limbs and the sensation as if a tight band were being drawn about the patient. He asserts that the effect of the methylene blue is very rapid and that the pain speedily disappears. In two or three hours the urine is colored blue. In this difficult class of cases Lemoine is of the opinion that methylene blue is one of our best remedies.

#### CHRONIC PROCTITIS.

In *Mathews' Quarterly Journal of Rectal and Gastro-Intestinal Diseases* for January, 1898, the subject of chronic proctitis is considered by TALLEY. He calls attention to the fact that we have two varieties of non-specific chronic proctitis: (1) Those cases in which a diffuse, persistent inflammation, superficial ulceration and papillomatous vegetations are the prominent features; (2) those in which the submucous tissues are principally involved in a hypertrophic process causing the proliferative stenosing proctitis. This latter condition is often engrafted on the first, and both conditions may coexist in any case.

In the first class of cases ulcerations are rather common, and these ulcers are usually in the lower rectum. This condition follows very readily the acute inflammation from any cause in a chronically congested rectum in patients whose power of resistance has been weakened by any cachexia.

The main symptom of this form of proctitis is slight tenesmus with frequent mucopurulent stools, these being at times streaked with blood; indeed, in some cases a large

quantity of blood is constant in the discharges and forms the most prominent feature of the case. The sphincter muscles become so relaxed in some cases as to cause fecal incontinence. The patient becomes weak and very much emaciated. Unless the inflammation involves the mucous membrane encircled by the sphincter, the patient will experience very little acute pain; however, there is usually a feeling of extreme discomfort in the rectum. When these symptoms have existed for a number of weeks or months it is sure that the patient is suffering from some form of chronic proctitis, and a thorough examination should be made at once. A digital examination may reveal the presence of ulcers when situated low in the rectum; however, this should not satisfy the physician, even if it be a fact that a majority of the ulcers are within reach of the finger. The entire rectum should be thoroughly inspected in every case, and to do this it is necessary to use the proctoscope. It should be remembered that the mucous membrane has, normally, rather a congested appearance, and when healthy may be mistaken for disease if compared with mucous membrane of other parts of the body.

Rest in the recumbent position is of paramount importance in the treatment of this form of proctitis. The diet should be of a liquid character, bland and nutritious. It is usually a difficult matter to properly diet a patient unless he is placed in an infirmary and carefully watched, for if treated at home, when he begins to improve and becomes very hungry some improper food will be given in spite of directions.

It is best in most cases to dilate the sphincter muscle, especially when the trouble is low in the rectum. When this is done the patient's bowels should first be thoroughly emptied with an aperient and the rectum washed out with a solution of boric acid; then the patient is anesthetized and the muscle paralyzed. After this the rectum is thoroughly inspected, and any ulcers discovered touched with a solution of nitrate of silver, forty to sixty grains to the ounce. Where there is no ulceration, but a diffuse chronic inflammation, the mucous membrane should be mopped with silver or copper of the strength of thirty grains to the ounce. The after-treatment consists in putting the patient to bed, washing rectum daily with warm boric acid solution, and the use of suppositories of iodoform and boric acid. A very useful injection in this condition is sweet oil and

iodoform, seven grains to the ounce, a tablespoonful to be injected at bedtime. These injections should be given with the hips elevated to prevent the oil from passing out.

In very chronic cases where the ulcers are extremely indolent, the solid stick of silver or crystal of copper may be used. In these cases it is necessary to make repeated applications before the ulcers become healthy and begin to heal.

It is stated by some authorities that we never find chronic proctitis in children. The author cannot agree with this statement, as a case came under his care a few years since in a boy four years of age. He had been passing considerable blood every time he went to stool for twelve months, averaging four or five stools daily. He had him anesthetized, dilated the sphincter, and examined the rectum as thoroughly as he could with a speculum. The mucous membrane was intensely red and granular. He applied freely a solution of silver, thirty grains to the ounce, over a surface somewhat larger than a silver dollar. The after-treatment consisted of washing the rectum with a warm boric acid solution and the injecting of a tablespoonful of sweet oil with three grains of iodoform at bedtime. This little patient was much better the day after the operation, when he passed very little blood. From that time on he steadily improved, and in six weeks was perfectly well. This was over two years ago, and he has had no recurrence of the trouble. During the twelve months he suffered he was continually taking medicine with no relief.

In very sluggish ulcers it is well to scarify or curette them before any application is made. Some works recommend enemata of starch-water and laudanum to relieve pain, but in the author's experience, where much pain exists it is due to some trouble in the sphincter area and is promptly and permanently relieved by divulsion of the sphincter muscle. He does not favor any medication of the rectum except that which is stimulating, antiseptic, or cleansing. In extreme cases, where the above treatment fails to cure and the disease is situated just above the sphincter, involving only a small area, it may be excised and the healthy membrane brought down and stitched to the skin at the anal margin, just as it is in Whitehead's operation for hemorrhoids. Papillomatous vegetations should be destroyed by chromic acid or the thermo-cautery. When they are high in the rectum and cannot be reached with a specu-

lum, the authorities advise splitting the rectum and anus back through the median line to the coccyx, to gain access to the trouble; but the author believes we will probably never have a case that cannot be effectually treated through the proctoscope. Very rarely a case may present with a tumor too large to be treated in this way.

The main feature of the proliferative stenosing proctitis is the involvement of the submucous connective tissues in a fibrous hyperplastic process which causes a thickening of the rectal walls and subsequent contraction and stenosis of the rectum. In this variety all the normal structures of the rectum are matted and fused together, the normal endothelium is changed, and the glands become atrophied. In some cases the inflammatory process extends into the perirectal tissues.

The lower half of the rectum is usually the seat of trouble, and in most cases it does not extend more than two or three inches above the sphincter muscle. There is rarely more than one point of extreme contraction, and there may be a chronic superficial ulcerative proctitis both above and below the constriction. The lumen of this stricture may become very small, but rarely closes entirely, as the passing of feces keeps up a certain amount of dilatation. This form of proctitis usually follows and is a late stage of the chronic ulcerative variety.

For the deep tissues to become affected it is not necessary for these ulcerations to be extensive, but just sufficiently large to admit the infection. In some of these cases we get a history of syphilis, but in none of them has the author been able to cause any absorption or disappearance of the inflammatory products by administering antisyphilitic treatment. So it appears that if the primary lesion was of a syphilitic nature, it only acted as a simple ulcer in opening up the structures of the bowel to deep infection. An inflammatory thickening of the rectal walls due to tubercular infection is usually accompanied by extensive tubercular ulcerations and evidences in other parts of the body of tuberculousis.

A patient suffering with stenosing proctitis will notice an increasing difficulty in defecation. In the morning there is often a feeling of urgent necessity to evacuate the bowels, but when he goes to stool he strains long and accomplishes little, and does not experience that relief which follows a thorough evacuation. He frequently passes little hard balls of fecal matter, and when the constrict-

tion is low the mold of the fecal mass will somewhat resemble a lead-pencil or a small tape. In this condition it is very easy for obstruction to occur from a blocking of the small passage with hardened feces. More can be learned of this condition by digital examination than in any other way. Instruments cannot be used on account of the constriction. By the finger you can distinguish a diffuse thickening of the rectal walls with a constriction in many cases, which will not allow it to pass. Strictures due to the healing of ulcers have a different feeling; they are irregular, and sharp bands project into the bowel. Carcinoma of the rectum may be eliminated by the history of the case.

This stenosed condition of the rectum never recedes spontaneously, nor is it benefited by any internal medication. It may be treated by palliative means or dealt with in a radical way. The best palliative method is to dilate as much as possible with elastic bougies and continue to pass them, at intervals, indefinitely. The Wales bougie is to be preferred, as it is hollow, and water may be passed through it while it is being introduced, to press the mucous folds out of the way and keep the instrument from catching in them. These bougies should not be passed oftener than every five days.

When the stricture is very resistant, an internal proctotomy should be performed to facilitate dilatation. There is little danger in this operation when the stricture is not more than two inches above the sphincter muscle. After internal proctotomy it is generally advisable to forcibly dilate the stricture with an instrument made especially for the purpose. Even after the latter procedure it is a good plan to pass soft-rubber bougies occasionally to avoid a recurrence of the stenosis.

#### CONTUSIONS OF THE ABDOMEN.

DEMONS (*Revue de Chirurgie*, No. 11, 1897) read a paper before the French Surgical Society upon this topic. He pointed out that as a result of traumatism applied to the abdomen the parietes could be injured, or the parietes together with internal organs, or the internal organs alone without demonstrable lesion of the parietes. The first question to determine is whether there is any visceral lesion. The muscular resistance offered by the abdominal walls varies in different individuals, also in the same individual according to the point at which force is applied and the condition of contraction or relaxation under

which the muscles are found at the moment of injury. Post-mortem experiments have shown that an astonishing degree of force is necessary to rupture viscera because of the resistance offered by the rigid muscles. This resistance, of course, is done away with when an injury is inflicted during sleep or when the patient is profoundly drunk. It is very great when the blow has been inflicted at the moment of violent muscular effort. The direction of traumatism is most important. If it is perpendicular to the walls its effects are more dangerous; if glancing, it is not so likely to injure the internal organs. Moreover, viscera are more vulnerable at certain times; thus, a distended stomach is much more readily ruptured than one which is empty, and pathological alterations in the walls of the intestinal canal render it more easily ruptured. Wandering viscera are more readily injured than those normally placed, and adhesions fixing organs prevent them from flying away from force. The symptoms vary greatly; sometimes these are very slight; sometimes they are extremely well marked. Between these two extremes there is every grade of severity. Pain is nearly always present. It may be limited, diffuse, or even radiating to other regions. It may be spontaneous or provoked. Clinical experience has shown that it is often more intense in contusions of the parietes, that it may be insignificant and transitory in visceral ruptures. Ecchymoses and tumefactions have no symptomatic value; this, also, may be said of one or two vomitings of the contents of the stomach and of slight tympany. Rigidity of the belly is, however, highly characteristic and sometimes accompanied by moderate tympany; it sometimes develops with a perfectly flat belly. It commonly accompanies rupture of hollow organs. The important general symptoms may be entirely absent or extremely well marked. Usually they are expressed in the form of shock. This when present is significant, but when absent by no means excludes the presence of most serious internal lesions.

The determination of the particular viscus wounded, the nature of the force and its point of application and the seat and nature of the pain are extremely important. Later local and general symptoms of internal hemorrhage are extremely characteristic, and finally the appearance of certain symptoms which we know are associated with lesions of certain viscera may complete a satisfactory symptomatology, so that diagnosis in a con-

siderable number of cases is not only possible, but even readily made shortly after an accident; thus extensive ruptures of the liver, kidney, or even the spleen, can be recognized without much difficulty, but it must be remembered that in a considerable number of cases the nature of the injury will remain obscure.

As to the exact portion of the organ injured and the presence of single or multiple lesions, this must necessarily be a matter of conjecture. As to the evolution of these cases, there are cases of apparently slight severity which promptly and permanently recover; others of these apparently favorable cases become worse for a time and then recover; others suddenly become extremely grave; others recover for a time and then later become extremely severe. Others, severe from the first, recover after a time and then become extremely grave; in others the outlook remains grave from the very first.

In forming the diagnosis insufflation of hydrogen has not proven successful and is attended with dangers. Exploratory puncture is likewise to be condemned. Exploratory laparotomy is the method of choice and would be universally adopted if it were absolutely inoffensive; however, it requires the administration of an anesthetic and should only be adopted when the possible advantages arising from it more than counterbalance its inconveniences. It should be practised immediately when the *ensemble* of symptoms suggest from the first rupture. It should be delayed in cases which are at first apparently trifling, but later become serious, or when it is necessary to allow the patient to recover sufficiently from shock to justify intervention. Late intervention is indicated when cases which are apparently trifling assume a serious aspect. Medical treatment is practically that applicable to shock.

---

#### THE TREATMENT OF TETANUS BY ANTITETANIC SERUM.

BORNET (*Gazette des Hôpitaux*, 1897) reports a case of tetanus recovering after ten injections of antitetanic serum. The disease developed after the patient worked eight days in the hold of a vessel, unloading sugar sacks. There was no distinct wound, and the author concludes that the infection took place through abrasions of the hands and possibly through the lungs. The disease began with trismus; the next day it was followed by violent general contraction be-

ginning with the cervical muscles and involving the back. Five days later the muscles of the legs were attacked, whilst the arms were not involved at all. The patient came to the hospital eight days from the beginning of his disease and the next eleven days received ten injections, each of ten cubic centimeters of antitetanic serum. He recovered completely.

[It is evident that this patient was attacked with a light form of tetanus and one from which patients not uncommonly recover spontaneously. From the meager report of the case it is difficult to determine whether or not the treatment was especially efficacious.]

## Reviews.

---

**PATHOLOGICAL TECHNIQUE.** A Practical Guide for the Pathological Laboratory. By Frank Burr Mallory, M.D., and James Homer Wright, M.D. Philadelphia: W. B. Saunders, 1897.

The work under review, as the title indicates, is a guide for the pathological laboratory, giving the methods for preparing and studying morbid tissues of all kinds. In addition it furnishes directions for conducting post-mortem examinations and bacteriological investigations, both clinical and experimental. The descriptions are clear and most accurate. Everywhere there is the evidence of abundant personal experience on the part of the authors, and the various methods recommended are described in such manner that the student will appreciate at once that the authors have found the methods useful when carried out as they describe them. An important advantage of the book is the heavy-faced type used for headings and titles of methods. This is of very great importance in all works intended for laboratory reference.

We need not enter into a review of the separate chapters. They are uniformly good. It may be well, however, to call attention to a few deficiencies. We should have been pleased to see the writers incorporate a short chapter on the aniline dyes, to give the student a general idea of their relative and general properties. The multiplicity of stains, many of them nearly alike in character and action, and many others quite dissimilar though nearly alike in name, proves confusing to students, and would warrant the introduction of a section such as we suggest. Perhaps the authors take a different view, and of course such a chapter is not strictly a

requisite. The sections on examination of the stomach contents, the blood, sputa, urine and feces deal with matters really more closely connected with clinical medicine than pathology. They are very short and in comparison with the rest of the book imperfect and unsatisfactory. It would have been better in our estimation to have omitted them entirely rather than to introduce them in their present form, in which, as the authors state, they pretend only to present what is of interest to the student in pathology. These remarks apply especially to the parts on urine, feces, and gastric contents.

Notwithstanding these slight blemishes the work is the most satisfactory guide of its kind in our language.

A. S.

**A SYSTEM OF MEDICINE BY MANY WRITERS.** Edited by Thomas Clifford Allbutt, M.A., M.D., F.R.C.P. Volumes I, III, and IV.

New York: Macmillan & Company, 1896 and 1897.

While a number of excellent works, of an encyclopedic character, dealing with the practise of medicine have appeared in American medical literature within the last ten or fifteen years, no such work of English authorship of equal importance has been compiled. In the *GAZETTE* for June, 1897, we reviewed the second volume of this series, because that was the first one sent us, and pointed out at that time that the publishers had been fortunate in obtaining an editor so well qualified to carry out a rather difficult task. From a reading of that review it must have been evident to all that the plan of the series was admirable, and those who are fortunate to have had the opportunity of reading the other volumes so far published must be favorably impressed with the practical utility of all the text.

The opening of the first volume on the *Prolegomena*, with articles on topics introductory and fundamental, is written by such well known men as, among others, Billings, Hutchinson, Burdon-Sanderson, Leech, Eustace Smith, and Dyce Duckworth. The articles upon the Fevers, which follow in the next part, are models of condensed information, so stated as to be useful to the practitioner, but they are not as a rule so exhaustive as in some of the American works on *Practise*. Perhaps the most noteworthy are those chapters on Diphtheria, by Gee, Thorne Thorne, Kanthack, and Herringham; on Enteric Fever, by Dreschfeld; and on Puerperal Septic Disease, by Playfair.

In the third volume we find the Diseases

of Obscure Causation, such as Rheumatism, Gout, Diabetes, Rickets, Acromegaly, etc. Of the authors of these articles the best known to our readers are Garrod, Cheadle, and Saundby. Following the articles on these subjects we come to the next section, on Diseases of the Alimentary Canal. The opening chapters in this section are on the Pathology of Digestion, by Ralfe and Fenwick; on the Pathology of Secretion, by Rose Bradford; and on Shock and Collapse, by Cobbett. Why these last named conditions should be considered in this place is not clear. The article on Dilatation of the Stomach is naturally written by the Editor, who was one of the first to study this important condition. By a curious division of labor Treves writes on Acute Peritonitis, while Acute Peritonitis of Undetermined Nature is written upon by Allchin. In the part on Disorders of the Bowels we find interesting articles by such men as Brunton, Rolleston, Hale White, and Treves.

The fourth volume, on Diseases of the Liver, of the Kidneys, of the Lymphatic and Ductless Glands, Diseases of the Respiratory System, and of the Nose, Pharynx and Larynx, is slightly smaller than its predecessors. The articles in it are quite up to the high standard set for it by the preceding issues, and the names of the authors are equally well known to the profession in this country and in England. What could be more appropriate than that Lafleur should write on Amœbic Dysentery, Hunter on Diseases of the Liver, and Henry Morris on the Surgical Affections of the Kidneys; or finally, that Ord should write on Myxœdema or Felix Semon on Diseases of the Larynx or Pharynx. The character of the authors is a guarantee of the value of their contributions to this very notable work, which will possess the advantage to American readers of presenting the subjects in a somewhat different manner from that to which they are accustomed.

**DISEASES OF THE EYE.** By Edward Nettleship, F.R.C.S. Revised and edited by W. T. Holmes Spicer, M.A., M.B., F.R.C.S. Fifth American from the sixth English edition. With a supplement on color blindness by William Thomson, M.D. Cloth, \$2.25.

Philadelphia and New York: Lea Brothers & Company, 1897.

Nettleship on the Eye has become a classic in the literature of medicine. This is due to the fact that it presents the reader with the very important facts in ophthalmology and leaves the discussion of the more abstruse facts to the larger and more exhaustive works

on this topic. In other words it is emphatically the book on the eye for the beginner in ophthalmology and for the general practitioner of medicine. Even the trained ophthalmologist finds it valuable, and often turns to its pages. Whenever the views of our English cousins clash with those commonly held in America the American editor points out the variation and makes the text conform to American views. The chapter on color blindness is of course particularly authoritative. Originally good, the book has been improved with each edition and now represents the advanced ophthalmology of the day.

**A CLINICAL TEXT-BOOK OF SURGICAL DIAGNOSIS AND TREATMENT.** For Practitioners and Students of Surgery and Medicine. By J. W. MacDonald, M.D. Illustrated.

Philadelphia: W. B. Saunders, 1898.

The attractive title of this book suggests the aim the author had in view and which he clearly expresses, to the effect that the rapid advance in the art of surgery makes it necessary to issue systems of surgery in many volumes, and text-books of large dimensions are now deemed necessary to cover the field. As a matter of fact the physician wishes to know first what is the disease or injury and next what is its proper treatment. Considerations having to do with pathology and bacteriology are omitted. The author states that he has taken great care to make the examination of each disease or injury systematic and comprehensive, and, when possible, directions are laid down as to the methods of examination.

The scheme is an extremely attractive and practical one, and provided it is carried out in a scholarly and systematic manner the book is likely to be of much greater service to the general practitioner than are the large systems that have recently been put upon the market. A review of the book is at once convincing as to the conscientiousness with which MacDonald has performed his work. Practically all the modern and approved operations are described with gratifying thoroughness and clearness. The illustrations are copious, excellent, and apt. There is a noteworthy absence of digression from the main points at issue and of that confusing minutiae of detail in describing comparatively unimportant symptoms or operations in which the author may happen to be personally interested. The book can be heartily recommended, and there can be little doubt as to the favor with which it is likely to be received by the profession.

## Correspondence.

### LONDON LETTER.

BY RAYMOND CRAWFURD, M.A. OXON., M.D., M.R.C.P.  
LOND.

In our last letter we referred to the discussion at the Royal Medical and Chirurgical Society on the prevention of enteric fever, which has now been brought to a close at a second meeting. At the opening debate the matter was mainly discussed from the point of view of the public health officer, but Dr. Payne discreetly pointed out the unreasonableness of such an attitude. If we assume that enteric fever is in the strict sense a specific disease, and that each fresh case can and does only arise from a preexisting case, obviously the medical man at the bedside should be the first line of defense. If by close antiseptic precautions the disease can be hemmed in at the bedside, there will be no need for the enormous labor of examining water-courses and water-supplies. We are too apt to look upon feces as the sole vehicle of the specific infection, but only recently two cases have come under our observation where the disease was almost certainly carried in the saliva from one patient to another, by drinking out of the same cup. Feces are very readily dealt with because, although in most houses the ideal method of burning them is impracticable, they may be rendered quite harmless with corrosive sublimate solutions. On the other hand the disinfection of bedclothing is very insufficient. Linen and cotton fabrics can be dipped in carbolic solutions and then boiled, but the same treatment cannot be meted out to woollen and flannel garments and blankets without damage to them; and for these articles there is the same objection to the use of corrosive sublimate solutions. Where disinfecting ovens are handy, these of course supply an obvious means of disinfection, but we still require some convenient method of dealing with these articles in private houses. Incidentally Dr. Payne expressed a belief that the theory of infection by inhalation of the typhoid micro-organism was something more substantial than a popular phantom. Indeed, Dr. Tivy sought to substantiate this view in the case of the Clifton epidemic, which Dr. Davies, the medical officer of health in Bristol, had conclusively traced to a polluted milk supply, as we mentioned in our last letter. Dr. Tivy maintained that this epi-

demic of enteric fever was due to sewer-gas poisoning from want of ventilation of the main drains, a condition that was intensified by the drought prevalent in August, September, and October. Sewer-gas seemingly found its way back into the houses, and especially into those situated in the higher parts of the town. Inasmuch, however, as Dr. Tivy did not marshal even the ghost of an argument in support of his views, it would be absurd to maintain his assumption against the detailed and elaborate conclusions of Dr. Davies' report. This appears, too, to be the view of the medical practitioners of Clifton, who have risen unanimously in support of their medical officer of health.

On Friday, November 26, the Clinical Society resumed their discussion on the treatment of angular deformity of the spine by immediate reduction. Mr. Watson Cheyne expressed himself as skeptical of the value of this method of treatment. He was surprised that the ill effects recorded were so few. General tuberculosis so often followed upon the forcible straightening of a tuberculous joint that one would have expected the same accident in dealing similarly with the spine. Then, again, it is impossible to conceive that the large gaps in the bodies of the vertebræ can be filled in by newly formed healthy bone, and there is but little justification for attempting Cabot's plan of securing posterior ankylosis by laminectomy. It is extremely doubtful whether better results are obtained by this method than by the double extension method as commonly practised in this country. Mr. Noble Smith agreed with Mr. Cheyne that time alone could pronounce a verdict on the procedure. For the present it seemed desirable to rest contented with the operations that had been performed, and to see what would be their outcome after two years had elapsed. He cited cases to show that much greater danger of general dissemination of the tuberculosis existed than the recorded cases would suggest; and in one case the new bone that had been formed in the gap of the vertebral bodies in the course of two and a half years was so soft and friable that it could not be said that any useful repair had taken place at all. For those interested in the details of the procedure we would call attention to an attractive article by Mr. Tubley in the January number of the *Practitioner*. This journal is now entering on the fourth year of its transformed existence, and holds an undisputed supremacy over all rival publications

in this country. To this end nothing has conduced so greatly as the indefatigable energy and judicious piloting of the editor, Mr. Malcolm Morris. We are looking forward to seeing its pages adorned by articles from the pens of our American brethren. Several other modifications have been introduced into the new series with a view to making the journal more definitely practical and clinical than heretofore.

The General Medical Council has succeeded in exciting general disapprobation by at last doing something. Their resentment has fallen on the head of the already much-to-be-pitied unqualified assistant. He is to cease to exist, and that forthwith. We have no wish to defend the existence of the unqualified practitioner, but seeing that he has been tolerated for years, and that in many instances this very tolerance has led to his existence, we would have given him a longer rope with which to hang himself. As it is, he is doomed to disappear, and we shudder to think of the prospect provided for the families with which in many instances they are cursed. We cannot but think that the Council might have found some more desirable object on which to exercise its punitive zeal.

At the Pathological Society of Manchester Dr. Raw showed a case of acute tuberculosis of the pleura, and made some remarks on the treatment of this condition. In his case, as so often happens, the pleura was affected without any invasion of the lung tissue. Few will be found to quarrel with his dictum that probably all cases of pleurisy are of microbial origin, and that cold is at most a predisposing agency, lowering the power of the lung to resist the activity of micro-organisms. It will also be pretty generally conceded that the large proportion of pleurisies, especially of insidious origin, and not occurring in the course of any specific or septic disease, are tubercular in origin. In this connection Dr. Raw recommends that as much of the infected pleura as possible should be removed and scraped away in operations for empyema due to recognized tuberculosis of the pleura. But therein lies the difficulty that the tubercular nature of the process is seldom demonstrable because of the extreme rarity with which tubercle bacilli are found in empyemata of almost certainly tuberculous origin.

In the *British Medical Journal* of December 4, 1897, Dr. Thin calls attention to the curative effects of milk diet in cases of intestinal derangement. Every physician is aware

of the readiness with which many cases of obstinate diarrhea, even of a dysenteric type, yield to rest in bed and an exclusively milk diet. Dr. Thin's observations refer especially to cases of psilosis, in which unmistakable signs of systemic poisoning were present in the patients until milk was substituted for other nutritious articles of diet. Even so, we have to decide whether the removal of other food substances or the adoption of the milk diet was the cause of the improvement. Dr. Thin inclines to the former alternative and suggests that some ferment can develop in such foodstuffs which cannot grow in milk or its products during digestion. Certainly in psilosis one of the most marked features of the intestinal flux is the abnormal degree of fermentation manifested in the evacuations. If a lightly boiled egg or a cupful of arrowroot is capable of producing a severe relapse, we may pretty safely assume that it is the presence of food materials other than milk in the intestine that encourages this abnormal fermentation. In other words, the virtues of a milk diet are rather passive than active. Incidentally Dr. Thin mentioned a case of lupus erythematosus that had completely healed under an exclusively milk diet, but subsequent experience of the same treatment had confirmed the *post hoc* but not the *propter hoc* of the cure.

At the meeting of the British Balneological Society Dr. Snow drew attention to the increase of intemperance from the administration of coca wine to invalids. This is in nearly every instance a strong alcoholic beverage containing more or less of one of the preparations of the *Erythroxylon Coca*. Thus the patient is exposed to the danger of contracting not only the alcohol habit, but the coca habit as well. Women who have not the hardihood to openly procure alcohol over the counter, will demand it without a blush under the innocent name coca wine, or a still more enticing French title. Many mothers, too, who would hold up their hands in holy horror at allowing their children to taste wine, allow them to resort freely to the bottle of coca wine, believing it to be as innocuous as it is palatable. We fear the practise would come into even more general use if the attractions depicted in a recent work on pharmacy were more widely known: "The subject experiences an exaggerated sense of *bien être*, a feeling of veritable beatitude, both mental and physical, expressing itself in incoherent

flights of the imagination and an abnormally acute consciousness of muscular vigor." The charms of opium and alcohol pale before this beatific vision.

We regret to say that the Council of the British Medical Association, acting upon the resolution passed at the general meeting in August, has sent reply-paid postcards to all the members of the Association, inviting an answer to two questions: (1) Are you in favor of the Association undertaking the duties of medical defense? (2) Are you willing to pay a special subscription of not less than five shillings, or more than ten shillings, for this purpose? As yet we have no information as to the result of this plebiscite, but we cannot conceive the likelihood of a majority of the members favoring such a proposition. The large majority of members joined the Association for the purpose of keeping themselves abreast of advances in modern medicine and surgery, and not to subsidize their medical brethren in fighting out their professional squabbles. It is impossible to see what even visionary advantage can accrue to the Association from taking on its shoulders a burden which has hitherto been satisfactorily borne by an absolutely independent Medical Defense Union.

Mr. Symons Eccles read a paper before the Medical Society of London on the Mechano-Therapy of Movable Kidney. Sixteen cases had been treated by him by the "rest cure," with special attention to abdominal massage and exercises for periods varying from fourteen days up to eight weeks. Out of eight patients who submitted themselves to a prolonged course of treatment, five were very greatly improved by abdominal massage, exercises, and the application of the pad and belt; one of these had been free from all discomfort for five years, and another for two years after suffering a prolonged period of discomfort prior to the treatment. No one will quarrel with Mr. Eccles over the benefits obtained by rest and recumbency in cases of movable kidney, but it is difficult to see on what possible theory massage can check the mobility of a dislocated kidney. For our own part we have long since discarded any belief in the efficacy of the pad and bandage, although in some cases its presence seems to charm away some of the subjective disturbances so commonly associated with the condition. If any interference can be considered justifiable, nephrorrhaphy at any rate has the merit of being a rational line of treatment.

## BERLIN LETTER.

BY JAMES J. WALSH, PH.D., M.D.

Two things are prominent in therapeutics in Berlin as we begin the year. One is Dr. Frenkel's (of Heiden, Switzerland) treatment for locomotor ataxia by means of exercises calculated to teach coordination once more; the other is the therapeutic effect of diet in health and disease. The former has been the subject of special demonstrations in at least two of the medical societies recently, and is constantly referred to by the clinicians. When there is a consensus of opinion among men who differ so widely on certain points in nervous diseases, especially in reference to tabes, as Leyden, Jolly, Mendel, Gerhardt, Oppenheim, and Remak, one can be sure that there must be some very convincing reasons for their agreement.

The idea of the movement treatment is to teach the patient again the coordination of muscles and the muscular sense that he has lost by the gradual involvement of the fibers of his posterior columns in tabes and related nerve affections. It would seem utterly visionary at first thought to hope for improvement in incoordination due to the fact that the sensory paths no longer convey to the consciousness the relative positions of parts and the state of contraction of muscles. That walking could for instance be taught again after it had been lost through an organic lesion involving that complex of sensations which goes to make up the equilibrium sense would seem incredible, but that is not only what is claimed for the Frenkel treatment, but is actually being accomplished by it in every prominent nervous clinic in Europe.

Patients who have been bedridden for years because of absolute inability to regulate their muscles for walking, get out of bed and learn even to go up and down stairs. A case at the Salpêtrière in Paris, which had not been out of bed for six years, now walks the streets without a companion. To one who knows how ataxics lack the confidence to go alone in busy streets, this means a great deal. Corresponding cases that have been bed-fast for three, four and six years, and even longer, have been reported here.

So much it seems necessary to say as a preliminary about the results because the treatment is so simple. It consists in putting the patient through the simplest exercises with the parts that are especially ataxic, but

requiring him to do them with the greatest exactness possible. If for instance he is confined to his bed, he is asked to put the heel of one foot on the kneecap of the other leg. First this is done with the aid of his eyes, then with the eyes closed. In a surprisingly short time this movement, which is so often used to show the presence of ataxia, can be performed very exactly and promptly. It was from experience with something like this that the treatment originated. A distinguished neurologist, about to give a clinical lecture on tabes, had a rehearsal of his patients beforehand in order to see what sets of movements particularly demonstrated the ataxia of each case. The patients were told they would be put through these before the class. Becoming a little anxious about doing them well, many of the patients repeated the movements a number of times beforehand, with the result that they utterly spoiled the demonstration.

After the exercises in bed the patient is put on his feet, and with proper support put through the motions of walking. He is asked to put one foot forward a little distance, then a greater distance, then toward the side, then backward. Each time it is pointed out just where he should put it, so as to teach exactness and reestablish the muscular sense and the sensations of coordination. After a while he is able to dispense with supports. So far as muscular strength goes the ataxic has no need of support. It used to be a favorite demonstration of Duchenne's to have some of his heaviest pupils mount the backs of ataxic patients, to show there was no lack of muscular power.

After a certain number of exercises the patients no longer need to watch their every movement with their eyes, but can walk with their eyes slightly raised, then looking straight ahead, and finally with eyes closed. Only two bits of technique are insisted on in carrying out the exercises: first, every movement must be done with the greatest possible exactitude, otherwise the whole aim of the treatment is lost sight of, as it is not exercise in the narrow sense of the word, but training not to overdo movements, that is, needed; second, a movement seance must never last more than seven to ten minutes. Owing to the disturbance of the sensory paths tabetics have lost the proper sense of fatigue, so the exercises may easily be overdone, and an intense tired feeling with great discouragement result. The accomplishing of exact movements seems to need supreme tension on the part

of the higher cerebral motor centers—a straining of the mental attention, as it were, to catch the faint inklings of muscular and position sense that come filtering up through the degenerated sensory columns. This must always be taken into account, and not more than two short seances allowed a day.

The contraindications would seem to be very few. Where the tabetic process is very acute, where the lightning pains are frequent and severe, and where there exist *severe* bladder and rectal disturbances, the patient usually is the worse for persistence in the treatment. Old tabetic cases, where the pathological process is practically at a standstill, are especially suitable for the treatment. All are benefited to some degree; those patients least in whom some inquiry into their past history reveals the fact that they were always a little awkward—*i.e.*, were always afflicted with a natural ataxia.

In the preataxic stage—and the more exact diagnostic methods of these last few years have made this period easily recognizable—the employment of the exercises has in a number of reported cases prevented the development of incoordination. Besides, in tabes the exercises have done good in certain hysteric tremors, pareses, and incoordinations. In multiple sclerosis, as might be expected, and in the “intentional tremors” generally, they are very effectual in restoring coordination; in neuralgias, especially sciatica, they have given good results; while in paralysis agitans they have relieved the sense of constraint caused by the muscular rigidity, which in these last few years has come to be looked upon as so essential a symptom of the disease.

I have spoken only of the reteaching of coordinate movements of the legs, but a great deal of good can be done also for incoordination of the hands. Here the exercises are necessarily for the accomplishment of finer movements—writing and the like—and really good results are not easily attained. I have seen two or three patients who had acquired a very legible handwriting after having lost the power to write anything but an illegible scrawl. In this, of course, a great deal depends on the legibility of handwriting in the preataxic days. As to the coarser coordinate movements required, in eating for example, or buttoning clothes, these can undoubtedly be retaught very satisfactorily in the great majority of cases.

I said at the beginning that the other feature in therapeutics here was diet. Two

things serve to bring it into prominence just now: first, the excellent results that are being accomplished in the treatment of tuberculosis in sanatoria, where careful diet adapted to each patient is one of the main features; second, the recent appearance of the first volume of Professor Leyden's book on Diet Therapy. Professor Leyden is said to be able to feed patients on more varied diet than any man in the profession, and secure more specific results from dietetic treatment. In some of his recent lectures he has touched on dietetic questions, and I have thought that some of the points would be interesting to the readers of the GAZETTE.

He says, for instance, that when tonics and appetizers have failed of their purpose for him, he has often had salted or acid or spiced foods create the desired appetite for food—for example, herrings, caviare, sardines, pickles, salads, carbonic acid drinks, or food flavored with lemon or spiced with mustard, horse-radish, or pepper, or watercress, and the like. Most of these things I think are often considered as absolutely unsuitable for sick people.

For chronic constipation Professor Leyden seems to have two favorite dietary additions for patients with whom they agree—plentiful sour milk, and cooked or preserved fruit eaten at night before going to bed. He prefers a sort of fruit soup for this, the preserves being allowed to stand in boiled water for some eight to ten hours before being eaten, in order to thoroughly soften them.

As warming drinks in cases of chill, besides the addition of alcohol he believes in the caloric influence of sugar. Sugared liquids and chocolate owe their undoubted warming influence to this fact. For sleep he finds that a light collation before going to bed—sometimes no more than a glass of milk, a biscuit or two, or an apple—frequently make a more effective hypnotic than drugs. In weak, overtired patients, especially in asthmatic cases, he has often had a cup of coffee taken at midnight, after an hour or two of hopeless sleeplessness, bring the much desired sleep. Mohn (a kind of indigenous poppy, the seeds of which are often scattered over bread here) and lettuce are excellent dietary somnifacients. For many people, in his experience, smoking acts as a hypnotic.

Professor Leyden, like Professor Ewald, Dr. Boas, and some other of the practical clinicians here, does not seem to put over-much faith in the all-nutrient power of milk. The opinion is generally expressed that it is

not alone sufficient to support life. As to just what is needed in addition to it for perfect nutrition all are not agreed. At least milk sugar should be added, according to Ewald, while some others think that additional fat, as cream, or albumen as in eggs, is needed.

Professor Leyden seems to occupy a position apart from most people with regard to mother's milk. He considers that it possesses specific properties which should cause it to be classed among the remedies we owe to organo-therapy—that it is something very different from a mere composition of nutrient materials. The old belief that some of the qualities of the mother or the nurse may be drawn in with the milk he does not consider absolutely unfounded. He even offers the somewhat startling suggestion that the present almost universal use of cow's milk for the nutrition of infants may have an unfavorable influence on the development of generations to come.

At a recent meeting of the Society for Internal Medicine Dr. Frank presented two cases of facial neuralgia that had become so unbearable that there was question of operative interference. Both had gone the rounds of the specialists and had tried all the known antineuralgics. In one case a single Pravaz syringe-ful, in the other two such injections, of a one-per-cent. solution of permanganic acid gave complete relief, lasting now for more than a year in each case. Professor Eulenberg, who has used the remedy in some thirty cases, says that while it does not always give relief, it often gives marvelous results and should always be tried before operation is resorted to. It must be injected directly into the substance of the nerve, and this causes considerable pain for a time after the injection. There are no complications or sequelæ of the treatment. For sciatica it is necessary, according to Dr. Frank, to cut down and expose the nerve to insure the remedy getting within the nerve sheath.

---

#### *EXTRACTION OF A BROKEN WATER TUMBLER FROM THE RECTUM.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: On the 1st of October A. R., an Italian, was brought to the private hospital of Dr. T. T. Koenig in Coulterville and gave the following history: The previous evening, while intoxicated, he was dancing naked in his cabin when he slipped and sat down violently upon a water tumbler which stood

upon the floor base upwards. The glass was partly broken by the fall, but the major part of it entered the anus and passed into the rectum base uppermost. The patient claimed to have lost "gallons" of blood; but his pulse was good and there was no hemorrhage worth mentioning. As it was late in the evening when he arrived, operation was deferred till next day.

The following day (October 2) operation was performed by Drs. G. M. Hawkins and T. T. Koenig. Dilatation of the anus allowed of thorough examination, which showed the tumbler firmly wedged in the rectum, the sharp points being towards the anus and firmly embedded in the sphincter muscle. Posterior rectotomy having been performed, an effort was made by means of two Sims specula to provide smooth planes on which the jagged points could slide out while the glass was pulled upon by curved forceps inserted behind it. But this failed because the blades of the specula could not be inserted between the rectum and the sharp points of glass. The external excision was then lengthened upwards, the coccyx dissected clear of soft parts and removed. This gave sufficient room to allow of manual extraction, the mucous membrane being retracted on both sides by the large forceps already placed in position to check hemorrhage. The bleeding was slight considering the extent of the incision. The rectum was then sewed up and afterwards the skin, a tampon being placed in the rectum and a drainage tube in the wound.

The following day the patient had a passage from the bowels, and when the wound was dressed was able to stand up; and at the latest accounts was doing well. The glass when extracted measured 1.9 inches at its base, was three inches high, and 2.5 inches wide at its mouth.

G. M. HAWKINS, M.D.

COULTERVILLE, CALIFORNIA.

#### *INGROWING TOE-NAIL.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: In a personal experience of an ingrowing toe-nail, the excision of the nail or portion of it was not favorably considered. The nail was thickened, with a tendency to contracture. Relief without an operation was secured by removing the pressure of the shoe upon the toe, excising a crescent out of the nail, leaving the ends pressing upon the edge of the matrix, paring the middle of the

nail down as thin as possible, and elevating the end of the nail by a pledget of cotton. An application upon the raw surface of a four-per-cent. solution of cocaine rendered the placing of the cotton under the nail painless. This cotton was changed every forty-eight hours. In a fortnight the toe was well and the nail was not disfigured.

A toe-nail is like a barrel hoop; when thick in the center it contracts well, when thin it expands. The ulceration is due to the contraction of the edge of the nail upon the edge of the matrix. The thinned nail, like the hoop, will expand and in this way cure the ulcer by removal of cause.

Respectfully,

B. H. DETWILER, M.D.

WILLIAMSPORT, PA.

#### *CAUSE AND PROPHYLAXIS OF BALDNESS.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: The question of baldness is one that forces itself on most men at some time in life, but why women should be nearly exempt is a question that has puzzled me for a long time. The common theory that baldness is due to the wearing of heavy headdresses has long been held as the correct one, and to which the hat-maker has catered by placing ventilators and other devices in hat crowns to insure a supply of fresh air. The theory is, I believe, entirely erroneous. We find hair growing on parts of the body, as in the axilla, where air is to a great extent absent and the conditions unfavorable to the growth of hair, yet it persists to the end of life.

Again, although women as a rule wear light headdresses, yet they nearly always wear a thick mat of hair which must keep the scalp as warm as a heavy cap, and this during summer and winter; yet it is rare to find a woman with a bald head. Of course, I am not speaking of baldness due to disease, such as eczema, syphilis, etc.

The following incident gave me a clue to what I consider the true theory of baldness: A farmer had a horse he was going to exhibit at the fall fair, and to add to his appearance he braided the tail, turned it up on itself, and secured it with a rubber band placed about six inches from the root of the tail. This was left on for a few days, and the result was that in the course of a few weeks nearly all the hair came out of the tail. The constriction cut off nutrition, and the follicles were starved, the hair eventually falling out.

The blood-supply to the scalp is conveyed by the frontal, temporal and occipital arteries, situated just where a tight hat would press on them and bring about a gradual starvation of the hair follicles. A woman, on the other hand, wears her hat resting lightly on top of the head, bringing no pressure whatever on the arteries, and thus escapes baldness. The maximum of hat pressure in a man comes on the frontal arteries, and in consequence we find baldness generally commences on the regions supplied by those vessels. To escape this affliction we must henceforth wear our hats on the back of the head or make hat-makers study anatomy.

#### *A CASE OF POISONING BY CONVALLARIA MAJALIS.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: My excuse for this communication is the rarity of recorded cases of poisoning by convallaria majalis, in contrast to the number of cases in which another drug of the same class—digitalis—has produced toxic effects. While this scarcity of cases is probably due to the fact that digitalis is prescribed so much more frequently than the lily-of-the-valley, another factor has undoubtedly some influence, namely, the preparations of convallaria differ widely in the proportions of the active principles which they contain, and many of them are practically inert.

Annie E., aged two years, was given nearly a teaspoonful of medicine, which her mother supposed was the fluid extract of cascara sagrada. About an hour later the attention of the mother was called to her mistake by the peculiar actions of the baby, and I was hastily summoned. I found that the bottle was labeled fluid extract of convallaria majalis.

The child seemed extremely restless, rolling and tossing about the bed, showing a continuous trembling of the arms and legs, with general convulsions once. She was aroused with great difficulty, and immediately relapsed into a stupor again. The pupils were dilated moderately. Axillary temperature 97° F., pulse 140 at times, and again so rapid that I was unable to count it, but always exceedingly irregular. Respirations were shallow and superficial, increased somewhat in rapidity, but very regular. The face was somewhat flushed. There was at no time any signs of gastro-intestinal irritation, and neither diuretic nor diaphoretic effect was observed. Under symptomatic

treatment the child gradually regained her normal condition.

This case was one of unusual interest to me because the literature on the subject is scanty, and opinions in regard to the physiological action of the drug so diverse. It furnishes another illustration of the gross carelessness of some persons in leaving medicine bottles scattered about the house, and using them freely without even the precaution of looking at the label.

#### *A CASE OF POISONING BY HONEY.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: Mr. D., an attorney, aged fifty-four, on July 26, 1897, shortly after his midday meal, at which he had partaken freely of honey, felt a strange feeling come over him: an incessant burning of the forehead; all sorts of objects, wheels, strings, etc., appeared to pass before the eyes; his face felt flushed, but he was pale.

I saw him about one hour after his meal. There was extreme pallor, cold skin; heart weak and irregular. He was in a dazed condition; the eyes had a dull look, and he complained that he could not see.

I gave him an emetic (ipecac), but he soon had convulsive movements of the hands, which were controlled for the time by holding them firmly. A minute following there was a convulsion of the whole body. He did not become rigid, but unconscious, limp, and exhausted. His breathing was heavy and fast. This was soon followed by free vomiting. Consciousness now began to return. He had no recollection of what transpired during the few minutes previous to vomiting, and now complained of cold and exhaustion. I gave stimulants, whiskey and aromatic spirit of ammonia in hot water, and applied heat externally. It was about seven hours before he was comfortably warm.

After seven hours the only remaining symptoms were widely dilated pupils, a tingling sensation of tip and sides of tongue, and a feeling of exhaustion.

The honey was in the comb, freshly made, and had a decidedly bitter taste. Of several boxes examined, this was the only one that presented anything wrong, and that only in taste. He ate about a quarter of a pound.

Yours truly,

C. D. VOORHEES, M.D.

## Original Communications.

### THE TREATMENT OF ACUTE INTUSSUSCEPTION IN YOUNG CHILDREN FROM THE STANDPOINT OF THE PHYSICIAN.\*

BY FREDERICK A. PACKARD, M.D.,  
Philadelphia.

I am led to write what follows partly by the comparative infrequency of intussusception, and chiefly by the fact that I refrained from employing the usual methods of treatment that lie within the field of internal medi-

cine as opposed to that of surgery. Justification for this course was found at operation, and my study of the literature of the subject showed plainly to me that the danger that I apprehended from non-operative mechanical interference was one that must not infrequently be present.

In contributing this case to the list of cases of intussusception I have selected from the large mass of literature a few cases that illustrate the points I wish to make, without endeavoring to add to the large number of statistical tables and articles dealing with this disease.

In regard to the frequency of intestinal invagination, I may state that since the foun-

\* Read before the Philadelphia Pediatric Society, Nov. 8, 1897.

dation of the Children's Hospital of Philadelphia, about forty years ago, no case of intussusception is found among the 7932 patients admitted to the wards before 1897. During the current year two cases have been admitted—one which came to the hospital during Dr. Griffith's term of service, the other which furnished the specimen shown to-night.

The child was a breast-fed girl aged eight months. She was first examined by me on September 18, two days after her admission to the Children's Hospital. She had then been ill for five days. The family history presented no features of interest. Until four weeks before her admission she had always been well and strong. At that time she began to have diarrhea and vomiting, her stools being bloody. These symptoms continued for ten days, during which time she was under treatment by a homeopath. At the end of the time mentioned she became better, but seems to have never entirely recovered her health. On September 13, three days before admission, the child began to vomit after nursing and diarrhea again set in, the stools being composed of blood and mucus. The number of movements was not excessive, there being but three on the day before admission. When brought to the hospital her temperature was 102° F., pulse 130, respiration 40. It was described by the resident physician as a well nourished baby with pale skin and mucous membranes, but without signs of rickets. The head was held slightly flexed, the neck muscles rigid, the pupils equal and natural. The two lower central incisors are noted as just emerging through the gum. She was perfectly conscious, but moaned a great deal, and the eyes were kept in constant motion from side to side. The lungs and heart were normal, the abdomen not distended but quite hard. It was at once given a drachm of castor oil, the bowel was cleansed by irrigation, and albumen water was ordered as the dietary. During this first afternoon there was one movement, which contained blood. That evening her temperature rose to 104° F. and continued at that point throughout the night. Before morning there were two watery, brown movements containing mucus. On the morning of the 17th the temperature was still 104° F., the pulse 120, respiration 24. During this day and the following night the child vomited all food taken (albumen water) and had five brown bowel movements containing blood and mucus. When my attention was

called to the child on the 18th it was lying on its back, slightly inclined toward the left side. The cheeks looked sunken, the eyes heavy and dull with dark rings beneath. The skin and mucous membranes had a deadly pallor, but the pulse was of fair force and volume. The tongue was dry and coated. Examination of the thorax revealed nothing abnormal. The abdomen was slightly retracted, but the walls were relaxed and soft. No visible tumor was present, but by palpation there was found a mass extending from the costal margin to the iliac crest far over on the left side. The tumor was distinctly curved in shape, the concavity being toward the right; it was slightly movable, but did not vary in shape, size or consistence during examination. During manipulation the child occasionally gave a slight whimper, but there was evidently no severe pain produced by the examination. The right iliac fossa gave a decided feeling of comparative emptiness. On removing the diaper the anus was seen to be widely open, and a fringe of rectal mucous membrane projected beyond it. The sphincters were completely relaxed. Digital examination of the rectum revealed a tumor of soft consistence, situated about one and three-fourths to two inches above the anus, readily outlined by the finger, and with a slit-like orifice easily admitting the finger-tip at its extremity. The diaper contained a dark semi-fluid stool having an almost putrid odor and evidently composed in great part of blood. There was a slight admixture of mucus, but no recognizable fecal matter.

For reasons that will be given below I decided not to endeavor to reduce the invagination by injections or inflation, but communicated with Dr. R. G. Le Conte, at the time acting as surgeon to the hospital; and on finding that he could operate at an early hour, turned the case over to his care.

Dr. Le Conte has kindly furnished me with his notes of the operation in order that I might incorporate them with this report. At 4 P.M. on the 18th of September Dr. Le Conte had the child etherized, and then made an incision in the median line below the umbilicus to the extent of one and three-fourths inches. The mass felt in the left loin could be easily brought up to the surface of the wound. The intussusciens was formed by part of the transverse and the descending colon, the intussusceptum of the small intestine, cæcum, ascending and part of the transverse colon. Reduction was comparatively easy until the withdrawal reached a point

within an inch of the cæcum, when a considerable amount of force failed to advance it further. While Dr. Le Conte was attempting the reduction an assistant used upward pressure by a finger in the rectum. After some further manipulation, aided by passing a finger along the intussusceptum and separating it from the sheath as much as possible, the cæcum was finally delivered by firm traction. An enlarged mesenteric gland of the size of an almond was probably the cause of the difficulty. The peritoneum covering the invaginated gut showed spots of roughening, with absence of gloss. The invaginated bowel was dark in color, resembling liver, and the mesentery was very dark and much congested. Two perforated ulcers were found in the ascending colon a short distance above the cæcum. They were sharply defined, oval in shape, punched out, and with an opening on the serous side smaller than that in the muscular coat. The edges of the ulcers were very dark. No extravasation of fecal matter had occurred through these openings, and the surrounding peritoneum showed no sign of inflammation. The ulcers were closed with a continuous Lembert suture of fine silk and the abdominal wound sutured. The operation occupied about thirty minutes.

After the operation the child's condition was very bad, the skin being pale and "leaking," the pulse very rapid and weak. The temperature was 100° F., the respiration shallow and rapid. Death occurred about three hours after operation.

No general autopsy could be obtained, but permission was granted to reopen the abdominal wound. There was no sign of general peritonitis. The cæcum and ascending colon lay to the left of the median line. The specimen presented was removed and may be described thus: It consists of a small portion of the ileum, the vermiform appendix, the cæcum, and the colon as far as the splenic flexure. The transverse and ascending colon are much thickened, especially as regards the submucous coat. High up in the ascending colon, near the hepatic flexure, there are two lines of sutures representing the points of rupture found at operation. The serous coat of the large bowel is quite rough, especially toward the caput coli. On the anterior surface of the specimen, at the junction of the ileum and cæcum, is a layer of material looking like organized lymph. The invagination is thoroughly reduced. The ileocæcal valve is thickened, and its broad lips project fully four millimeters into the cavity of the cæcum.

There is decided thickening of the wall of the cæcum surrounding the valve.

To my mind there are several points of interest in the case. In the first place the diagnosis was easy because of the presence of bloody stools, a tumor readily palpable and of characteristic shape on the left side of the abdomen, and an easily recognized mass in the rectum. It is possible that this was a case of spontaneously reduced invagination with relapse. In spite of the presence of vomiting and bloody stools during the earlier attack, there was no other sign or symptom that could be found by questioning the mother, and that would warrant such a diagnosis. That such a late recurrence might occur is possible, Holt stating that in his collection of cases recurrence was noted in six per cent., and that while it was most common in the first twenty-four hours after reduction, it may occur at as long an interval as a month.

In this case there was no family tendency to the disease, such as has been noted by some authors (Bryant, Hirschsprung, and others).

As the child was first seen by me on the fifth day of its illness I endeavored to picture to myself the probable condition of affairs within the abdomen. This I felt must guide me in my course of treatment. I decided that by that time the invaginated intestine must have become much swollen from prolonged stasis of blood; that adhesions between the serous surfaces of the inner and middle cylinders had almost certainly formed; that sphacelation might already have begun from pressure upon the mesenteric vessels of the intussusceptum at the neck of the invagination; and that ulceration of the intussusceptum or of the sheath might very likely be present. I therefore decided that an attempt to reduce the invagination by injection or inflation would be fruitless because of adhesions, and dangerous because of the risk of perforation of the weakened and possibly ulcerated or sloughing cylinders. I therefore sent word to Dr. Le Conte that I considered the case one where the interference of the surgeon was alone justifiable. That such was the case is shown by the operation. Reduction by injection or inflation would have been impossible, not only because of the adhesions between the serous layers but by reason of the presence of the enlarged lymph node found at operation and seen in the specimen; while it would certainly not have saved life even if the invagination could have been

reduced, owing to the presence of the ulcerations that could not have been detected except at operation or autopsy.

Certainly but a short time must elapse after the formation of an intussusception before there is marked constriction of the blood-vessels (especially of the veins) of the intussusceptum. Not only is the mesentery necessarily crumpled up within the sheath, but there is so much distortion of the mesentery of the inner cylinders at the point of entrance that the return flow of blood must be rapidly and seriously diminished. Such a sudden interference with circulation must produce marked swelling of the intussusceptum from engorgement of the blood-vessels and from transudation into the tissues. At the same time the intussusceptum tends to become turned upon itself owing to the fact that the mesentery going to the apex is in a state of greater tension than is that of the proximal portion of the gut. According to Treves the thickening of the intussusceptum may be universal, but is usually most marked at the apex and along the convexity. The opposed serous surfaces covering the inner layer of the middle cylinder and the outer layer of the inner tube are in close juxtaposition and are placed in circumstances readily leading to the formation of adhesions. Prolonged interference with the blood paths leads to impairment of vitality in the two inner cylinders from faulty nutrition and from mechanical separation of their component parts by transudation from the engorged vessels. Sooner or later loss of substance occurs from either ulceration or sphacelation. According to D'Arcey Power, the stress of the trouble is borne most often by the submucous tissue and by the circular layer of muscle, the longitudinal muscular and serous coats being least affected. The sheath may not entirely escape, as in some cases it is found ulcerated, at times at many points. The impact of the apex of the intussusceptum may be sufficient to produce local ulceration of the sheath, which may perforate. General peritonitis, however, is not frequent, partly no doubt because the diseased mass is usually, so to speak, encapsulated by a fairly healthy cylinder whose mesentery has suffered no damage. The small amount of involvement of the sheath and the obstruction of return flow from the intussusceptum may limit the spread of the colon bacillus and other organisms, in that way accounting for the fact that Holt found among fifty-eight collected autopsies only

twenty cases showing peritonitis, in seven of which it was limited to the intussusception, while in seven there was perforation.

The conditions militating against reduction are, then, swelling of the intussusceptum, bending of the intussusceptum upon itself, cohesion of the entering and returning layers, adhesion of the serous surfaces in contact, and finally (a point brought out clearly by Braun) plication of the sheath near the point of entrance, whereby the sheath is much thickened and the neck of the sac rendered more rigid. In the case herein reported there was a still more powerful impediment to reduction in the enlarged mesenteric gland. I have nowhere seen this mentioned as a cause of irreducibility, yet it is easy to conceive of the possibility of its frequency. In the ileocæcal form, with which alone I have dealt, the swelling of the lips of the ileocæcal valve forms a distinct obstacle to reduction. The mechanism of this obstruction can be well seen in the specimen.

Statements regarding the time at which the various changes in the intussusceptum take place vary widely. Most authors state that the earliest time for the formation of adhesions is the third day, although many give the fourth as the usual time. They are, however, often absent at an even later time. Sphacelation is usually a rather late event, of necessarily variable rapidity and degree in different cases, although Jalaguier states that it generally first shows itself at the end of from two to three days, while Wiggin cites a case with gangrene of the gut twenty-eight hours after the onset, and Broca encountered gangrene at the end of thirty hours.

The exact time of occurrence of these various accidents which may prevent reduction or render it dangerous when performed without inspection of the parts involved cannot be laid down absolutely. A few cases from literature will serve to show this uncertainty in time of development. Mortimer, in a three months' old child which died thirty-six hours after the onset of an intussusception that was supposed to have been reduced by insufflation, found already a little soft lymph at the point of reflection and some injection of the sheath. D'Arcey Power describes a specimen removed from a nine months' old child dead thirty-six hours after the onset of the illness. There was very little, if any, thickening of the mucous membrane, but the surface was covered by a layer of coagulated blood.

There was edema of the whole submucous layer and also extravasation of blood and formation of inflammatory products therein. The veins of the submucosa were congested, and this layer contained many huge capillaries. There was also edema of the circular and longitudinal layers of muscular tissue. Adhesions throughout the whole extent of the adjacent serous surfaces of the inner and middle cylinders were found by Rotch in a case dead on the third day. In a child aged eight months that had been ill for three days with intussusception, Power found all parts of the invaginated intestine seriously damaged, with great congestion of the blood-vessels, round-celled infiltration, extravasation of red blood cells, and dense adhesions between the serous layers of the two inner cylinders. Bryant records a case in a child aged six months admitted on the second day of the disease. On the day after admission (only the third day of the illness) death resulted promptly after insufflation of the bowel with air; and at autopsy there were found two perforations, one at the splenic, the other in the sigmoid flexure. Pilz found a small oval opening near the beginning of the intussusception which had perforated into the peritoneal cavity and caused death on the fourth day of the disease. In Wiggin's paper perforation is stated to have been present in two of his cases on the fourth day, although in both of these injections had possibly caused the lesion and the cases should not be considered in estimating the lesions present on the fourth day of the illness. Mortimer records a case wherein gangrene was established on the fifth day, to offset which a case is reported by Wiggin where adhesions were absent although the lesion had existed for the same length of time. Bryant records a case of ulceration present at the point of constriction at the entrance on the fifth day of the disease, and another wherein on the seventh day there was sloughing of the mucous membrane near the ileocaecal valve without any adhesion between the serous layers. Mortimer gives a case dead on the eighth day with three ruptures in the descending colon, one of which had rounded edges as though several days old.

It will be seen from these examples how variable is the extent of pathological changes in different cases at various periods after onset. Unfortunately without actual inspection of the parts involved we have no means for exactly estimating the conditions that may be present in a given case.

It would seem from the examples selected that practically at no time can we be absolutely sure that no contraindication to an attempt at reposition exists. As a matter of fact, however, there is a sufficient number of cases reported of cure following injection or inflation to make it advisable to attempt reduction by these measures during the early course of the disease.

The question as to the period during which it is justifiable to resort to mechanical (non-surgical) methods by distention of the bowel is important, not only from the standpoint of probable success or failure, but also in regard to safety. A few opinions in regard to this point may be selected. Eustace Smith says that mechanical interference is only permissible during the first few days and is useless if the mass be tender. Ashhurst says that injections are most likely to be successful in the first two days, but after that period should not be tried. Rotch states that in "the early hours" attempts should be made to reduce by hydrostatic pressure. Starr gives the first four days as the limit of time for the use of distention, but not even then if the mass be tender. Holt says that if three or four days have passed without symptoms indicating strangulation, it is admissible to try more than two inflations at intervals of three or four hours. Keen gives the first forty-eight hours as the time during which alone distention can do good, and that after that time has elapsed there is danger of rupture. Monti says that better results occur in early cases than in those existing for many days; nevertheless he holds "as fully justifiable the view already pronounced by authors to in all cases try water irrigation or air insufflation." Jalaguier says that distention is only to be tried if the case is seen at the onset. Leichtenstern rather vaguely states that "if the invagination has lasted for some time, if it has become fixed and chronic, or if there are signs of gangrene and impending separation, if general peritonitis or perforation is present, no prudent physician will make any attempts at reduction."

It may be said, then, that all mechanical attempts at reduction should be performed with the greatest care and gentleness, that they should be employed at as early a time as possible, and that after the third day they promise but little success and are capable of doing great damage.

At the present time no one would venture to support the plan of allowing (in young children) Nature to effect a cure by separa-

tion of the intussusceptum—a plan that has, according to Treves, a death-rate of forty per cent. among the forty-two per cent. in which separation takes place when the case is left to Nature. According to Widerhofer, among the forty-six cases of the combined tables of Leichtenstern, Pilz, and himself, where separation occurred, seventeen died, twenty-seven survived, while in two the result was unknown; and, he adds, even in these so-called cases of recovery death usually occurs in from one to two years. In very young children (and especially in infants) death may be expected before Nature has had time to cast off the slough.

All authors are in accord regarding the use of opium before all non-sanguinary efforts at relief, although the exact form and channel of administration advised differ somewhat. Thus, Eustace Smith and Rilliet and Barthez advise the subcutaneous use of morphine, while almost all other writers recommend the use of opium or laudanum by mouth or rectum. Monti has urged the employment of a warm bath for its relaxing effect before any measures are employed. Anesthetization by chloroform or ether is universally advocated.

Considerable difference of opinion exists regarding the advisability of employing abdominal massage as an aid in reduction. Thus, Hirschsprung recommends that it should be tried before injections are employed, while Jalaguier condemns it as useless and dangerous. It is difficult to appreciate in what way it could be of great value, while the danger of exciting peristalsis, and so defeating its object, would seem to contraindicate its use. Of the various media for use in the mechanical reduction by distention may be mentioned water, air, olive oil, milk, thin gruel, and normal salt solution. Of these water and air are most generally recommended. Whatever medium may be selected, it is important that we should be able to accurately measure the amount of force that we are employing. This is most easily calculated in the case of water or watery solutions entering by gravity, and is practically impossible in the case of air or gases unless we happen to have at hand a compressed air apparatus or cylinder with pressure gauge. The use of solutions, union of which in the bowel will cause the evolution of gas, must manifestly be extremely dangerous inasmuch as we have no means of estimating the distending force exerted upon the bowel wall.

It must be remembered in using fluids that the pressure exerted by them acts equally in all directions and that, unlike a solid means of reposition, such as the discarded and in practically all cases useless sound, it does not simply exert its force in the direction of the lumen of the bowel. The advantage which this property gives is that, while pressure is exerted at the apex of the intussusceptum, the sheath is at the same time distended, thereby removing it from the intussusceptum and thus aiding the retrogression of the latter. The very fact of this lateral as well as forward pressure is, however, a distinct source of danger.

The most rational fluid for use, to my mind, is normal salt solution, owing to the fact that it is readily obtainable, is bland enough to prevent any irritation save by its bulk, and causes no disturbance by osmosis.

The temperature of the fluid used is a question whereon there is some difference of opinion. Most authors recommend the use of warm water (100° to 105° F.), but no less an authority than Baginsky states that it is better to use cold than warm water. Monti, the strongest advocate of the use of iced water enemas, begins irrigation with tepid water and at the conclusion of the process uses a half to one liter of iced water in order to induce peristalsis while pressure is high and to so reduce the invagination. He relates the case of a seven months' old child, seen on the fourth day of its illness, where repeated failure followed the use of the sound and injections of tepid water, but on the sixth day the injection of a liter of iced water was successful. Elliott mentions a case in which inflation with air and injection with warm water failed, but an enema of iced water was successful on the second day of the disease. Henoeh relates several cases in support of this plan, but in some of his cases the diagnosis must be considered doubtful, as he himself seems to admit. Iced water is condemned by Leichtenstern, who ranks it with turpentine and carbonic acid water as promoters of peristalsis. In this connection the question suggests itself whether peristalsis under any circumstances can aid in the reduction. If we grant the possibility of reversed peristalsis (anti-peristalsis) we can see how possibly such movement might aid in reduction; but it has not been proven, so far as I can find, that we can by iced water or by any other means start such a reversion of the intestine within the unopened abdomen. If reversed peristalsis is not excited by iced

water enemata the tendency would be for the excitation of peristalsis to cause further propulsion of the intussusceptum into the sheath. The volume pressure of fluid injected would probably neutralize this tendency to forward projection, in which case any good effects of peristalsis, such as are claimed by Monti, would be overcome. Peristalsis, according to the experiments of Cash, is a comparatively weak force, overcome in the dog by an opposition of from five to eight grammes. This, however, may not apply to an intestine in which excessive peristalsis is stimulated not only by the lesion present but also by the cold injections. If, therefore, the peristalsis is thus neutralized, it is difficult to explain any advantage to be derived from the use of iced water enemata, inasmuch as their property of coldness might seriously depress the vitality of the patient, and it is inconceivable that cold or any other astringent could diminish the size of the intestinal plug.

In giving enemata the position of the patient is a point of importance. The position usually advocated is that on the back with the hips elevated and the patient turned slightly toward the left side. Monti recommends the knee-elbow position; others, among whom is Baginsky, advise the inversion of the patient, a procedure characterized by Treves as "a violent measure which neither on theoretical nor on practical grounds has anything to recommend it."

It can be readily appreciated that one of the most important things to observe in the use of fluid pressure is the avoidance of such force as to cause rupture of the bowel. It is also necessary to bear in mind that the longer the lesion has persisted, the more marked are the tissue changes in the bowel wall and the greater is its liability to rupture. The exact determination of the resisting power of the wall of the bowel in an individual case cannot be determined, yet the supposition that the younger the lesion the higher the breaking-strain must be accepted as in general true. In order to determine the resisting power of the intestine to pressure, experiments have been tried upon the cadaver by various authors. Inasmuch, however, as the subjects used died from lesions unconnected with the intestinal tract, a few only will be mentioned here. Forest found that in the body of a child a few months old, after ligating the ileum a pressure of nine and three-quarter pounds to the square inch was required to rupture the transverse colon at

the middle of its anterior surface, and that when the small intestine was thus ligated in other subjects the point of rupture was never at the seat of obstruction, but in the colon. When the ileum was not ligated, in a case dead of marasmus, he says that "it seemed almost impossible to rupture the intestine by pressure, so long as the nose or mouth was pervious"—a condition that for practical purposes does not exist in intussusception, where the large bowel is occluded above the seat of pressure by the invaginated plug. Mortimer, on the other hand, in his experiments upon two-year-old children in the post mortem room, found that a pressure of two and a half pounds (five feet elevation) was apt to cause "cracking of the peritoneum," an occurrence that usually took place when the reservoir was raised to eight feet, and that at an elevation of six feet there might be complete rupture of the bowel. Mole found that in a child aged five years the colon ruptured after the passage of five pints of water at a pressure of four feet. These experiments, it must be remembered, were made upon children without grave intestinal lesion. More instructive, for our purpose, is Mortimer's experiment upon a child dead of intussusception. The patient, aged three months, was treated with supposed success by inflation. Death occurred at the thirty-sixth hour. A tube was passed into the rectum and connected with a reservoir at a height of two feet. In a few minutes there occurred partial reduction of the invagination. After fifteen minutes the irrigator was raised to three feet; this caused a slight increase in the reduction, but soon stopped, and in four minutes the colon ruptured in three places just below the invagination.

In using irrigation the fountain syringe is certainly preferable to those depending upon hand pressure, which is necessarily intermittent and incapable of measurement, while the steadiness of hydrostatic pressure prevents excitation of peristalsis and diminishes the danger of rupture from sudden increase of pressure. The height to which the reservoir should be raised is a question of importance. The extreme elevation that I have found recommended is that by Forest, who says that six pounds to the square inch (an elevation of fifteen feet) is safe within three or four days of the inception of the attack. The same author recommends, as preferable to performing laparotomy or depending upon cure by sloughing in children under six years

of age, a pressure of six pounds to the square inch, or, if this fails, to raise the pressure to eight or even nine pounds (twenty to twenty-five feet elevation). Most authors, however, are more moderate, and are unanimous, so far as I have consulted them, in condemning any elevation greater than eight feet, and usually recommend an initial elevation of three feet with a gradual increase in the height of the reservoir up to the point mentioned. Some authors recommend the higher pressures for the cases of greatest duration, the reverse, to my mind, of what pathology would teach as the proper rule.

The time after onset at which injection is practised has much to do with the success or failure of the method. Thus, Eccles has tabulated twenty-one cases in children. The number is small, but the effect striking. One of these was treated on the first day and recovered (recovery in 100 per cent.); six were treated on the second day, of which four recovered (recovery in sixty-six per cent.); eight were treated on the third day, of which two recovered (recovery in twenty-five per cent.); six were treated on the fourth day, of which none recovered. Holt has collected forty-six cases cured by injections or inflations. Of these, sixteen were treated on the first day, fifteen on the second, three on the third, eleven on the fourth, and one on the fifth day. Of the sixteen cases successfully treated by distention in Wiggin's table none were of more than three days' standing, the average time of cure being on the forty-first hour, while twenty-three cases that died had an average duration of sixty-nine hours.

That rupture can readily occur from distention is shown by cases related by Bryant, Wiggin, Mortimer, Widerhofer, and many other writers of analytical papers and monographs, as well as by many isolated reports in the medical journals. How many times the bowel has been ruptured by injections and inflations and the case not reported cannot even be surmised.

To return to my case, the subject of this paper. It is evident from the account given by Dr. Le Conte that an injection would have probably caused immediate escape of the fluid into the peritoneal cavity through the perforations found at operation. It is quite possible that, even if the bowel had not perforated, reduction could not have been completely effected owing to the presence of the enlarged mesenteric gland, and that a false assurance of successful reduction might have prevented the undertaking of further

attempts to save the child's life. It may be said that the child died at any rate. That is true, but it died after the best course in our opinion had been adopted; and I have not the uncomfortable knowledge that by my treatment I produced perforation of the bowel in a case that might have been saved.

It might be judged from what I have written that I do not believe in endeavoring to effect reduction by distention of the bowel. Such is not the case; but I do believe that injections are dangerous and oftentimes useless after the third day; that before that date, unless otherwise contraindicated, it is proper to attempt reduction by the use of one thoroughly executed injection, upon failure of which surgical aid should be at once summoned without loss of time from further attempts by a procedure that should be thoroughly and conscientiously applied in the first instance. I wish finally to protest against such a procedure as that advocated by one author, to keep the child in the hallway and to carry the reservoir of the irrigator up the stairway. The height of the ceiling of an ordinary room is more than enough to allow of the reservoir being elevated sufficiently to rupture the healthy bowel, to say nothing of an intestine seriously damaged by disease.

# THE REAL VALUE OF THE BRAND BATH IN TYPHOID FEVER.

BY H. A. HARE, M.D.,

Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia;

AND

CHARLES ADAMS HOLDER, M.D.,

Assistant in Therapeutics; Physician to the Department of Diseases of Children in the Southern Dispensary.

As its title indicates, the object of this paper is to discuss the real value of the cold bath treatment of typhoid fever by a study of the statistics and facts which are now before the profession concerning it. It is sometimes wise when a plan of treatment seems to be particularly effective to analyze its results to determine its real value, for as Cabot has well said recently in a paper on the routine use of alcohol in fevers, the progress of therapeutics is seriously hindered by the fact that every case is given the best treatment known, and so we are satisfied with it. We desire to state at the outset that we fully recognize the great usefulness of the cold bath of Brand, although it may seem in the course of our paper that we are attempting to cast discredit upon it. On the contrary we desire first to determine its actual value, and second to inquire whether its routine use is wise.

When the physician begins to study this subject he is met by the statement that the mortality, which was at one time no less than twenty-five per cent., can be reduced by the cold bath to from ten to seven per cent. As a matter of fact a mortality of twenty-five per cent. has not been commonly met with for many years, and the largest body of statistics yet collected giving this death-rate are those made in Germany and France many years ago, when the disease was particularly virulent, when only severe cases were recognized and classified, and further, when owing to what may be called barbarous treatment the patients who survived fought their way against infection and treatment. Further, hospital facilities were comparatively poor, nursing ineffective, and sanitation wretched.

That severe cases chiefly entered into these statistics is proved by the statements of Griesinger and Strümpel, who point out that numerous light and rudimentary attacks (typhus levisimus) were not recognized till lately as belonging to typhoid fever at all.

That the treatment was calculated to increase the mortality is shown by Vogl's statement that it consisted in venesection, emesis and catharsis, and free use of mercury. That

the hospital facilities were wretched in many instances as compared to those of to-day is notorious (see Baas, History of Medicine), and the history of individual cases and the results of the analysis of large bodies of statistics impress upon us the important fact that among the poor who have not hospital care, and in armies where the patients are not cared for when in the field as is possible when at home, the death-rate is very high and the signs of disease severe.

Improvement in sanitation has decreased the frequency and mortality of this disease remarkably, as is shown by statistics.

Mosny has shown that the death-rate of Vienna decreased from 12.05 per 10,000 to 1.1 after a pure water-supply. In Dantzic the mortality has fallen from 10 per 10,000 to 2.4, and finally to 1.5 per 10,000. In Stockholm it has fallen from 5.1 in 1877 to 1.7 in 1887. So too in Boston from 17.4 in 1846-49 to 5.6 in 1870-84.

The following table is of interest in this connection:

MORTALITY IN MUNICH FROM 1851 TO 1873.

Year.	Inhabitants.	Annual.	Per 100,000 Inhabitants.	Year.	Inhabitants.	Annual.	Per 100,000 Inhabitants.
1851..	123,957	123	99.0	1874.....	181,300	289	159.0

1871.....	170,000	220	129.0	1894.....	393,000	10	2.5
1872.....	169,693	407	240.0	1895.....	400,000	15	3.7
1873.....	175,500	230	131.1	1896.....	412,000	14	3.4

\*This table is taken from Pettenkofer's "Munich a Healthy City" up to 1887 inclusive; after 1887 from returns obtained from the Statistical Bureau.

The effect of improved sanitation is to decrease the virulency of infection, and for this reason there follows a decreased severity of illness and a decreased percentage mortality.

For these reasons then we shall exclude the statistics of 1840, 1850 and 1860 from comparison and confine ourselves to more recent statistics more suitable for this purpose. This is the more important when we discover that the frequency, severity and mortality of typhoid fever is steadily de-

creasing all over the world, as is shown by the following interesting tables of Dreschfeld in regard to England in general and London and Manchester in particular:

ANNUAL MORTALITY, PER MILLION PERSONS LIVING, FROM FEVER IN ENGLAND.

Period.	Enteric Cases.	Period.	Enteric Cases.	Period.	Enteric Cases.
1838.....	1228	1857.....	989	1875.....	371

1887.....	151	370
1888.....	169	330
1889.....	130	310
1890.....	146	270
1891.....	132	370
1892.....	702	240
1893.....	161	250

These figures are exhibited graphically in the following chart:

CHART NO. I.—SHOWING DECREASING MORTALITY OF TYPHOID FEVER PER MILLION PERSONS LIVING IN ENGLAND, LONDON, AND MANCHESTER.

Not only is the decrease in mortality seen in England, but in Philadelphia and New York, as follows.

The decrease in cases and in mortality is shown in the following chart in broken and complete lines (Chart No. 2):

CHART NO. 2.—SHOWING DECREASING NUMBER OF CASES AND DECREASING PERCENTAGE OF MORTALITY OF THESE CASES IN PHILADELPHIA.

Year.	NEW YORK.	Cases.	Deaths.
1888	1108	1108	364
1889	1414	1414	397
1890	1100	1100	354
1891	1348	1348	366
1892	1149	1149	400
1893	1008	1008	381
1894	792	792	326
1895	905	905	323
1896	1002	1002	297
1897	1004	1004	299

The following chart from the New York Health Report shows a decreasing death-rate from typhoid fever (Chart 4):

CHART NO. 4.—SHOWING DECREASING DEATH-RATE FROM TYPHOID IN NEW YORK CITY.

Broken line represents mortality per cent.

Year.	Cases.	Deaths.	Per cent. of mortality.
1888	3573	785	21.9
1889	4631	730	15.8
1890	3182	586	20.9
1891	3531	683	19.3
1892	2304	440	19.1
1893	2519	456	18.1
1894	2357	370	15.7
1895	2748	469	17.0
1896	2490	402	16.1
1897	2094	401	13.3

\*These statistics go back as far as the comparative records extend.

CHART NO. 3.—SHOWING DECREASING NUMBER OF CASES\* ANNUALLY IN NEW YORK.\*

\*A comparative chart of the number of cases and of mortality per cent. from these figures is not given, as Dr. Biggs, of the New York Health Office, writes that only recently have the cases been generally reported and even now many are not reported.

When we consider that the population of these cities has increased enormously the great decrease in the disease is very notable.

These tables are supported by the statement of Billings that in Norway from 1888 to 1891 the mortality from typhoid fever was 755 in 7467 cases, or less than ten per cent. In the present Maidstone epidemic the death-rate in 1885 cases is only 7.5 per cent., and a similar mortality obtained at Plymouth, Pa. Again, in the *Gazette Médicale des Hôpitaux* of July 10, 1890, we learn that a collective investigation showed that whereas in the period from 1866 to 1881 the mortality from typhoid was 21.5 per cent., from 1882 to 1888 it was 14.1 per cent.; in 1889, 13.5 per cent.

It is evident therefore that the mortality to-day should be placed at less than fifteen per cent. as a fair percentage, the more so as many years ago Murchison placed it at 17.45 among 27,951 cases in England.

Assuming, then, that the ordinary mortality of typhoid fever is at present about fifteen per cent., the question arises, How much credit is to be given to the cold bath method for the reduction, claimed by its advocates to be about seven or eight per cent.? It is well in this connection for us to remember that a disease that cannot be aborted and which runs a definite course till it is completed will

do less damage to the patient if the case is guided through the storm so that his natural processes are not perverted than if by meddling or absolutely harmful treatment his organs, already bearing the burden of disease, are still further strained by the influence of unnecessary drugs and by the necessity of absorbing and eliminating them.

The best treatment for typhoid fever is to let drugs alone so far as possible. It is evident, therefore, that if a given routine is followed which is manifestly not incorrect in its fundamental details, better results will be obtained than if each physician steers his patient on a course of his own choosing, which may not only be useless but actually dangerous.

This is shown by the facts presented by Liebermeister in his well known article in Ziemmsen's Cyclopaedia, in which he gives carefully prepared tables of 839 cases, of which 377 were treated non-specifically, with a mortality of 18.3 per cent.; 223 treated by full doses of calomel, with a mortality of 11.7 per cent.; and 239 with iodine, with a mortality of 14.6 per cent. If the grave cases are included in his statistics the mortality of a general plan of treatment was 25.3, those treated with calomel 16.3, and with iodine 17.2 per cent. A routine treatment here gave a saving of life nearly as great as the cold bath treatment often does, the difference between fifteen and seven per cent. Liebermeister adds that he has compared fifty cases treated with calomel, fifty with iodine, and fifty by general indefinite measures, selecting those admitted about the same time and all of whom were looked upon as grave cases in their early history. All the calomel cases recovered, and yet he rejected all cases which did not reach an axillary temperature of 104° F. or over.

Bouchard with intestinal antiseptics, quinine, cool bathing, etc., had a mortality of 11.16 per cent. as against twenty-one per cent. on the old general plan of treatment; while Mason records 676 cases with a mortality of ten per cent. under cool sponging, intestinal antiseptics in some instances, and symptomatic treatment. Under a similar plan Jaccoud lost out of 655 cases 10.8 per cent. Riess in 900 cases with the use of tepid baths had a mortality of seven to eight per cent., and under pure expectant treatment with plenty of water to drink Debove had at the Hôpital Andral 9.2 per cent. (See also Colle's statistics about to be quoted.)

Of very great interest in this connection are the results recorded by A. L. Mason in

the *Boston Medical and Surgical Journal* of April 14, 1892. During 1890-91 there were treated in the Boston City Hospital 676 cases of typhoid fever, of which seventy-five were fatal, or 10.4 per cent. This includes all cases—mild, moribund, or doubtful—which entered the house. To illustrate how statistics may mislead Mason records five different series of cases, aggregating 242 cases, with five deaths, or a mortality of about two per cent. The treatment consisted not in the Brand method, but in sponging and affusions, the use of antipyretic drugs, antiseptics, and tonics.

The following table contains a large number of cases treated without baths:

	Cases.	Per cent. of Mortality.	Treatment.
Basel (Liebermeister).....	223	11.7	Calomel.
Basel (Liebermeister).....	239	14.6	Iodine.
Maidstone, England.....	1,885	7.5	General.
Boston (Mason).....	676	10.4	General.
Homerton (Collie).....	677	9.5	General.
Glasgow (Collie).....	618	8.2	General.
Société Médicale des Hôpitaux (1879)*.....	1,979	12.47	.....
Jaccoud.....	665	10.8	General.
Riess.....	900	7.5	Tepid baths.
Boston (Shattuck).....	237	9.8	Expectantly and cold sponging.
Germany (?) Brand has collected.....	19,017	7.8	All kinds of cold baths.
	27,116	10.02	

\*These statistics are based upon the fact that twenty-one chiefs of hospital service reported to the Société Médicale des Hôpitaux (1890) 916 cases with 114 deaths, or 12.44 per cent., under general treatment; and for 1888 and 1889 this report also mentions 1063 cases so treated with 133 deaths, or 12.51 per cent.

In other words, 27,116 cases in Switzerland, America, England, Germany and France show that good nursing and careful non-meddlesome treatment will give a mortality of about ten per cent. It may be argued that these cases cannot be compared with cold bath methods, but the wide distribution of the cases and the large number of clinicians certainly give us what may be called a standard average. The reduction in mortality to ten per cent. is therefore due to good nursing and treatment, and the further reduction to 7.5 per cent. claimed by Brand advocates only amounts to about 2.5 per cent.

Admitting, then, that a harmless form of treatment with careful nursing naturally modifies typhoid fever, these factors must be deducted from the credit given to the cold bath of Brand (which gives 7.5 per cent.) before we can reach real facts as to the value of this plan *per se*, for in it careful nursing is a *sine qua non* to its use and only such medication is resorted to as is needed to control symptoms or accidents. Again, one other factor is not to be ignored, namely, that it is

an almost universal practise to use alcohol in the cold bath treatment, and this stimulation, often repeated many times a day, by means of a drug which lends force to the system, is to be credited with some effect. To emphasize still more the fact that good nursing and treatment modify the mortality without the bath, we can quote the figures of Collie comparing the death-rate in Basel with that elsewhere in the same years with and without the bath.

At Basel in 1873, under the cold bath, there were 163 cases with a mortality of 10.4 per cent.; during the same year at Glasgow without baths 275 cases with a mortality of 9.4 per cent.; and 305 at Homerton with a mortality of 9.5 per cent. In 1874 at Basel the water cases were 200 with a mortality of 10.5 per cent.; at Homerton 372 with a mortality of 9.6 per cent.; at Glasgow 343 with a mortality of seven per cent. As Collie well points out, it is likely that the cases in Glasgow with 500,000 population and East London with 1,000,000 would be more severe than in Basel, a county town of 40,000 to 50,000 people.

TABLE SHOWING MORTALITY UNDER GENERAL TREATMENT TO BE LESS THAN UNDER BATH TREATMENT.

	Number of Cases.	Treatment.	Mortality Per cent.
Basel (1873).....	163	Bath.	10.4
Glasgow (1873).....	275	General.	9.4
Homerton (1873).....	305	General.	9.5
Basel (1874).....	200	Bath.	10.5
Glasgow (1874).....	343	General.	7
Homerton (1874).....	372	General.	9.6

Before determining the value of a method of treatment from statistics derived from hospital practise it is necessary to ascertain the death-rate outside of that hospital and if possible for the entire city or surrounding country.

In this connection it is interesting to note that in Dr. J. C. Wilson's cases, recorded with great detail to the number of 108 as occurring in the German hospital from June 1, 1893, to October 1, 1894, and submitted to the most rigid type of bath treatment, the mortality reached 11.1 per cent., and that for the same two years 1893-94 the mortality in the whole city of Philadelphia, including every type of case and every plan of treatment, or none at all, was only 16.8; or in other words, the mortality of the bath treatment was only 5.7 per cent. less than that of the whole town. Again, in the series of cases which he has had since that time (October 1, 1894, to January 1, 1896), namely 117, he had nineteen deaths or a mor-

tality of 16.25 per cent., whereas for the whole city of Philadelphia the mortality was only about 15.3 per cent. Allowing for the fact that Dr. Wilson excluded from his cases patients who were admitted moribund, and that all of them were under the most approved and complete nursing and in the hands of competent resident physicians and a physician-in-chief of wide experience, it does not seem to us that the bath treatment has really given in this instance a very great degree of life-saving; and it must be recalled that while the percentage of deaths named by Dr. Wilson was a percentage derived from all (with the exceptions noted) cases in the wards, the percentage of mortality for the city was really far less than it would seem, for many physicians neglect to report cases unless they grow so ill that it is done at once before the death certificate has to be signed.

Considering the fact that patients are supposed to be greatly benefited by this treatment, if treated before the fifth day, it is a curious fact that out of fourteen of Dr. Wilson's cases (in 108) which received the bath by the fifth day no less than four died, and another case died which is stated as admitted early in the disease. It is also an interesting fact that while the general mortality of Philadelphia was decreasing progressively in 1890, 1891, 1892, 1893 and 1894 from 20.3 to 15.7 per cent., that Dr. Wilson's statistics should have an increasing mortality from 1.8 in 1890 to 11.1 per cent. in 1894, and 16.25 in 1894 to 1896. Owing to imperfect health reports we cannot discover the percentage of typhoid mortality in Baltimore to compare with Osler's cases.

The same difficulty exists in New York in regard to Gilman Thompson's and the city statistics. At the Philadelphia Hospital for the ten years from 1888 to 1897 inclusive the number of cases of typhoid fever and the mortality per cent. is shown in the following chart (No. 5). The practise of tubbing was not instituted till 1892. How rigidly it has been enforced we have not been able to determine, but it is evident that the mortality has not been materially influenced by this means. Thus 1888, 1889, and 1890 had a mortality without the bath identical with that after the bath was used in 1895, 1896 and 1897; and 1888, 1889 and 1890 had a mortality lower than 1892 and 1893 when the bath was used. We think therefore that it may be considered proved that a large credit should be given to other causes than the Brand bath, and this holds true not only for this country but

abroad, for most of Brand's statistics are derived from German military hospitals in times of peace, when everything tends to a mild course of the disease. The military sanitation, the close watch over each individual, the fact that a livelihood is not lost if the patient goes to bed early, all tend to render the disease mild and to cause cases to come under treatment early. Further, the patients are in the great majority of cases very young, just passing out of their teens. It is evident, therefore, that the cold bath in itself is not as useful as would appear at first sight.

CHART NO. 5.—SHOWING MORBIDITY AND MORTALITY PER CENT. AT THE PHILADELPHIA HOSPITAL FOR TEN YEARS, 1888 TO 1897 INCLUSIVE.

Solid line, morbidity; dotted line, mortality per cent.

There are certain objections to the cold bath in the sense of tubbing which must be met. The first of these is that by its use an unnecessary expenditure of the patient's strength ensues. No one can see for the first time a typhoid fever patient bathed without a feeling of mingled pity for the case and mistrust for the method. To use Osler's clever words: "When I hear a poor fellow (who has been dumped, like Falstaff, 'hissing hot' into a cool tub) chattering out maledictions upon nurses and doctors, I am inclined to resent it, and to pray for a method which may be, while equally life-saving, to put it mildly, less disagreeable." So much for sentiment and perhaps judgment. Let us see if there are other rational objections.

To remove a patient too feeble to raise his hand to his head into a tub of water some 35° F. colder than his body, which is accustomed to the heat of his bed, seems heroic, and the lifting and necessary handling must produce some loss of needed strength. Again,

the shock of sudden and complete immersion may or may not be harmful according to opinion, but the nervous awakening if really a good thing can hardly be looked upon without the thought that the nervous energy expended is unnecessarily great, and one wonders whether the same results for good could not be obtained by gentler measures. That they cannot remains to be proved. When it comes to permitting a patient to rise from his bed and step into the tub, then we believe the enthusiasm of the bath advocate oversteps the limits of good sense. Nothing can possibly be gained by this expenditure of strength and its strain on a heart taxed by fever, exhaustion, and toxemia. Even if strong enough at the time the patient should save such energy for some future crisis or to aid in his convalescence. If walking typhoid has a high mortality it is due to this lack of conservation of energy. It seems to us as unwise for a patient to arise and step into a tub with a possibly ulcerated artery in a Peyer's patch as for a case of aneurism to make any effort. The shock and altered circulation is sufficient strain on the blood-vessel without the additional strain of change of posture and of effort.

Thus Liebermeister says, although an ardent bath advocate: "It is possible that the determination of blood to the internal organs, caused by the abstraction of heat, may increase the tendency to hemorrhage; and at all events, the moving of the body, be it active or passive, connected with the taking of a bath, is injurious. The same thing, of course, holds true, to a still greater degree, in perforation of the bowels."

*Hemorrhages.*—The frequency with which hemorrhages occur varies greatly in different epidemics independent of any specific line of treatment over and above rest in bed. Lack of such rest certainly predisposes the patient to this accident. In 861 cases of this disease without the cold bath in Liebermeister's clinic at Basel, hemorrhages occurred seventy-two times, or in 8.4 per cent. Griesinger met with thirty-two cases in 600, or in 5.3 per cent.; and Louis found them in 5.9 per cent., excluding mild cases. The younger Wunderlich has recorded ninety-eight cases of typhoid fever without the bath with hemorrhage in two cases, or about two per cent. We find therefore that in 1559 cases treated without the cold bath there were ninety-nine hemorrhagic cases, or 5.2 per cent.

On the other hand we find that in bathed

patients Wunderlich, Jr., records 155 cases with sixteen hemorrhagic patients, or 10.3 per cent.; Immermann at Basel records 146 cases with six hemorrhages, or 4.1 per cent.; and Liebermeister 882 cases with fifty-five hemorrhages—1183 cases, or 6.8 per cent.

This is shown best by the following table:

WITHOUT BATH.

	Cases.	Hemor- rhages.	Per cent.
Liebermeister.....	861	72	8.4
Griesinger.....	600	32	5.3
Wunderlich, Jr.....	98	2	2
Totals.....	1559	106	5.2

WITH BATH.

	Cases.	Hemor- rhages.	Per cent.
Liebermeister.....	882	55	6.2
Immermann.....	146	6	4.1
Wunderlich, Jr.....	155	16	10.3
Totals.....	1183	77	6.8

To these may be added: In America, with baths, Wilson's 140 cases with ten hemorrhages, or seven per cent.; Osler's 356 cases with twelve hemorrhages, or 3.4 per cent.\*

It is interesting to note in this connection that Fitz places the general frequency at five per cent. and Loomis at five per cent. It is, however, only fair to state that Goltdammer from nearly 20,000 cases concludes that the bath does not increase hemorrhages. Brand claims they are less frequent, as do also Tripiet and Bouveret; but Roland G. Curtin tells us that upon investigation he found that since the cold water treatment has been instituted the number of hemorrhagic cases has considerably increased, according to the hospital records that furnish the data, and in addition the mortality of the hemorrhagic cases is largely increased, viz., from five in seventeen, less than one-half, to twenty-five in forty-three cases, or over one-half; and further, on inquiry he found that in two of his tabulated cases the hemorrhage seemingly took place while the patient was in a bath, and in one case immediately after a bath.

An important point in this connection is the question as to the real danger from hemorrhage to the patient. In this opinions greatly differ. Thus Fitz tells us that it is always a serious symptom, but rarely fatal in private life; but that it may be very disas-

trous is shown by the fact that Liebermeister mentions forty-nine deaths due to this cause out of 127 deaths, Murchison fifty-three deaths from hemorrhage out of 100 deaths, and Homolle forty-four per cent. in 498 deaths. Osler asserts that death occurs in from thirty-five to fifty per cent. of hemorrhagic cases. Out of Griesinger's thirty-two cases of hemorrhage ten died, seven of these within four days of the hemorrhage. Liebermeister tells us that among his own cases 38.6 per cent. died when they had hemorrhage as against eleven per cent. without this accident; and Tyson tells us that the seven per cent. mortality in his cases under the bath treatment was due entirely to hemorrhage or perforation. It is evident that Osler's percentage is about correct.

*Relapses.*—It is admitted by advocates of Brand's method that relapses are more common under its use than without it. Osler met with fourteen cases of relapse in 160 cases bathed, or 8.7 per cent., but mentions five other cases of doubtful relapse, which raises the percentage; while Shattuck met with 21 in 129 cases, or 16 per cent., and eleven occurred before primary fever ceased. Wilson tells us that it occurred in 11.3 per cent. of his cases, and Osler tells us 8.7 per cent.; Shattuck 16 per cent., Immermann 15 to 18 per cent., Baumler 11 per cent., and Jaccoud 9 per cent., varying from 1 to 15 per cent. As against this we may place the frequency as given under no bath treatment. Thus Murchison gives it at 3 per cent., Gerhardt in 4000 cases 6.3 per cent.; Griesinger puts it at 6 per cent., and Strümpel at 4 to 16 per cent.\*

At the Presbyterian Hospital in New York Gilman Thompson found the relapses in 193 cases to be 13.5 per cent., which is 2 per cent. higher than in 284 cases treated by all methods during the same time.

Liebermeister says: "In Basel, before the introduction of this treatment, 861 typhoid fever patients gave us sixty-four relapses, or 7.4 per cent., two of which were fatal; after the introduction of this treatment, 882 typhoid fever patients gave eighty-six relapses, or 9.8 per cent., ten of which proved fatal. *It appears, therefore, that the proportion of relapses and the number of deaths are both actually increased under the use of cold water.*" And discussing the probable bearing of these results he adds: "At present the probability

\*Only 299 were bathed.

\*It is not possible for us to discover if all the cases of Gerhardt and Griesinger were treated without the bath.

certainly seems to be in favor of the affirmative of the question, the more so as it appears that the frequency of relapses is greater in proportion as the antipyretic treatment has been the more systematically employed." Biermer has also found relapses more frequent since the introduction of cold baths.

On the other hand Murchison with his extraordinary opportunities places the percentage at three per cent.\*

Having determined the fact that relapses are more common under the cold bath, we must determine what are the dangers of a relapse. As a rule we believe relapses are milder than the primary attack, provided the primary attack has been severe.† On the other hand, if it has been rudimentary or in the class called by some writers "typhus levissimus," then the relapse is more severe. In any event the relapses are characterized by a greater suddenness of onset and usually a shorter course. That the relapse is an element of danger seems self-evident, since it comes on in a patient already exhausted by disease. Therefore the prognosis is grave according to the severity of the relapse and the state of the patient. It is interesting to note that in Liebermeister's cases out of 111 cases of simple relapse the fever was longer in duration than in the first attack in thirty-seven, shorter in sixty-eight, and of the same length in two. In twenty-nine of the cases the primary attack was mild and in eighty-two severe, but the relapses were mild in forty-seven and severe in sixty-four, and seven of these died in the relapse.

Other figures might be stated, but these seem sufficient to prove that relapses are dangerous to the patient and to be avoided if possible. This is still further emphasized by the fact that at Basel out of 115 relapses hemorrhage from the bowel occurred four times, perforation twice, thrombosis once, pulmonary consolidation nine times, nose-bleed seven times, bed-sores four times, abscesses five times, and petechiæ three times.

To quote Liebermeister again: "If we take the reports of the years 1869, 1870, and 1872, at Basel, we find, among 467 typhoid fever patients systematically treated with cold baths, thirty-three deaths and fifty-five relapses, six of which were fatal; the frequency

of relapses, therefore, counting only those patients who had survived the first attack, was in the proportion of 12.5 per cent., as against nine per cent. before baths were used. The higher rate of mortality among the relapses is of so much the greater import, in view of the fact that the relapses, too, were treated antipyretically, which ought rather to have given us a lower death-rate."

*Perforation.*—An interesting question is the effect of baths on intestinal perforation. What the ordinary percentage of this accident is is in some doubt, but according to Murchison it is in the neighborhood of three per cent., and this is about the percentage reached by Osler in cases bathed and not bathed.

The most interesting comparative statement as to the frequency of perforations with and without the bath is that made by Mason. Thus at Boston City Hospital the percentage of perforations in males was 1.4 and in females 1.3, while under the cold bath in Brisbane it was 3.6 per cent. in males and 1.6 per cent. in females—Liebermeister's statistics, viz., that there were twelve cases of this accident in 973 patients before the bath and fourteen in 1108 after it was introduced, show a very slight difference.

The mortality of this accident is very high. Of 1721 autopsies the percentage was 11.3, according to Murchison. According to Osler it was found in 2000 Munich cases 114 times (5.7 per cent.), and in twenty out of eighty of his deaths.

*Duration of Disease*—The influence of the bath treatment on the duration of the disease seems to be to prolong it. It is necessary to determine the ordinary duration with and without baths. Very important classifications of cases are those made by Liebermeister and Jurgensen. The first of these clinicians speaks of the mildest cases as those in which the rectal temperature never or rarely rises above 103°, and the duration of fever does not exceed eight days. Such cases require only dietetic treatment and cannot be used to show the value of different modes of treatment. The mild cases do not have a rectal temperature above 104.8°, and the fever lasts sixteen days. The severe cases are those in which the rectal temperature rises above 105° and the fever ceases by the twenty-first day. Jurgensen considers all cases mild which have no fever after the tenth day, and those severe that have fever after this date.

Murchison states the mean duration in seventy-five cases to be a fraction more than

\* It is interesting to note in this connection that in Wilson's cases out of twenty-five cases in which the bath was commenced within the first week there were no less than four relapses.

† Flint is the only author of note who thinks that the relapses are more severe than the first attack.

twenty-four days. Flint states from going to bed to normal temperature sixteen days, with a maximum of twenty-eight days and a minimum of five days. Longest case seen by Flint was fifty-eight days.

Of forty-five of Flint's fatal cases the duration was a fraction more than fourteen days. Murchison tells us that the mean stay in hospital of 500 cases which recovered was 31.24 days, of 100 fatal cases 16.52, while the average duration of illness before admission of the 600 cases was 10.78 days. Again, Murchison tells that the pyrexia as a rule lasts at least three weeks, and the ordinary duration of enteric fever is from three to four weeks. Of 200 cases which recovered, and in which he was able to fix the commencement with tolerable certainty, the duration was: ten to fourteen days in seven cases; fifteen to twenty-one days in forty-nine cases; twenty-two to twenty-eight days in 111 cases; twenty-nine to thirty-five days in thirty-three cases.

The mean duration of the 200 cases was 24.3 days, and the mean duration of 112 other cases, which were fatal, was 27.67 days.

The average duration of residence in St. Thomas' Hospital, London, in 1894, 1895 and 1896 was from 43.1 to 51.8 days, and the average duration of fever from 14.3 to 16.73 days, although a great proportion of the patients were admitted in the first or second week.

If we take the twenty-five cases admitted in the first week of the disease given in Wilson's table, we find that the average stay of these patients in the house was forty-one days (40.8), and the average day of normal temperature the nineteenth. The average maximum temperature was 104.6° (40.3). If the entire 108 given in his last table in his article are studied we find that the average duration of the fever was in the cases admitted in the second week 23.2 days, in the third week 27.3 days, and the average stay in the house of the second week cases 40.8 and of the third week cases 38.8 days. These figures would seem to contradict Wilson's statement that his patients as a rule return to their homes in two weeks from defervescence.

Gilman Thompson states emphatically that the cold bath does not ordinarily shorten the duration of the disease.

To summarize the points so far covered, we find that the mortality for typhoid fever to-day all over the world, except in the presence of individual epidemics of malignant infection, is not over fifteen per cent., and if

the cases receive good nursing and non-meddlesome treatment, about ten per cent. or less.

That in American hospitals under the best men in the profession the mortality of typhoid fever is about 7.5 to 8 per cent., and sometimes ten or even eighteen per cent.; therefore the saving of life by the bath is not the difference between twenty-five per cent. and seven per cent., but between ten per cent. and seven per cent. at the very best.

That this method does not shorten the attack but probably prolongs it.

That relapses are much more frequent under it.

That hemorrhages are more frequent, when in reality the modification of all the symptoms by the bath would lead us to expect a decrease in their number.

That the frequency of perforation is not decreased.

If the general mortality of fifteen per cent., as we have shown exists, is reduced to ten per cent. by good nursing and treatment, and the mortality under the bath amounts to about 7.5 per cent. at the very best, as it does in the hands of all American observers, it is evident that the cold bath is responsible for a saving at the most of but 2.5 per cent.; and it is also evident that this 2.5 per cent. is saved by the favorable effect of the bath on the nervous system, circulation, respiration, and the toxemia, for the other cases of death remain unaltered in frequency or are increased.

With the manner in which these good effects are produced we shall deal a little further on. It yet remains for us to determine what are the defects of this method, then to consider how it does good, and finally whether any better plan or modification can be adduced.

In the first place it would seem an opportune time to protest against the almost universal application of the bath to this disease. It is, or ought to be, a fundamental law of therapeutics that there is no such thing as treatment by hard and fast rules of routine. The recommendation that all cases of typhoid fever with a temperature of 102° to 102.5° F. shall be placed in a tub of water at 65° to 70° F. is an affront to this rational law. Until all human beings are exactly alike in every attribute and characteristic and all micro-organisms are possessed of equal virulence, power of multiplication, and growth, every case of infectious disease seen by the physician will require careful study if the best re-

sults are to be obtained. He must modify his treatment to fit his case. It may be that some general trend of method is suited to all cases just as a coat is needed by all inhabitants of cold countries, but each individual needs a modification of the coat to fit his figure and necessities. Digitalis is useful in twenty-drop doses in many cases of valvular heart disease, it is useful in other cases in smaller doses, and in some not at all useful; and even a specific remedy, like quinine for malaria and mercury for syphilis, is subject to grave modifications in every case we meet if the best results are to be obtained.

It must be evident that as the temperature is far more easily reduced in one patient than in another, the temperature of the bath should be modified to the case as well as the duration of the bath. Every one knows how in one patient with a temperature of  $104^{\circ}$  the temperature is easily lowered, while in another, because of the severity of the disease, an excess of fat, or other causes, the reduction can only be caused by great effort.

When we consider all the points in the cold bath treatment it is almost impossible to avoid the thought that it is a measure to which in a few years we will look back with the same distress that we regard excessive venesection and other excesses. We are now told to plunge practically every case of typhoid fever into a bath at  $70^{\circ}$ ; to keep the man, shivering, chattering and blue, in the water for some twenty minutes, then to lift him out on a bed, place a hot bottle to his feet, and perhaps elsewhere, and give him a drink of whiskey to overcome his feebleness, and chills. "Truly he is cast from the heights of pyrexia to the degradation of collapse, and then with a swift turn stimulated to renewed febrile efforts. That the mortality is decreased by this method may be partly true, but to use a simile, are we not using croton oil to move the bowels in all cases when cascara will do equally well in a number, and the croton oil is required only in a few?

These facts have been recognized by so many eminent men of very large experience that it would seem unnecessary to quote them were it not that followers of the cold bath plan have recommended its use in every case of the disease which comes to their hands. Thus we find one of the leaders in his enthusiasm for this method of treating this disease telling his readers that he has used it continuously for seven years, that it has been the "only treatment" in his wards, and that all patients suffering from this disease have

been submitted to it except very rare cases in which the axillary temperature has not reached  $101.5^{\circ}$ , those brought in in a dying state, and those admitted after the third week. He also stops the bath in the presence of hemorrhage and perforation. And again we are told that the patient receives a full bath at  $65^{\circ}$  to  $70^{\circ}$  every five hours when the rectal temperature reaches  $102.2^{\circ}$  or over. Other clinicians do likewise. On the other hand we find no less an authority than Strümpel making the following statements:

"In so far as the height of the fever furnishes an indication for baths, we may accept, say,  $103.6^{\circ}$  F. ( $39.8^{\circ}$  C) in the rectum as the temperature calling for a bath. At night we have given baths very seldom, except when forced to by extremely high temperatures or other bad symptoms. It must be a mistake to wake a patient who is quietly sleeping, and put him into cold water, even if his temperature is above  $104^{\circ}$  F. ( $40^{\circ}$  C.). Likewise, in cases where the temperature shows considerable spontaneous remissions, there may be no use in inflicting a cold bath upon a patient who has high fever only temporarily.

"It is not always advisable to use baths, however advantageous this treatment may be, in typhoid fever. There are a [number of contraindications which cannot be disregarded, as great weakness or great sensitiveness, such that the excitement caused by the bath might do harm. Sometimes baths are followed by severe rheumatic ('rheumatoid') pains in the limbs, and often they seem to promote the occurrence of furunculosis. In such cases it is often necessary to omit the baths, or at any rate to employ them less often and at a warmer temperature. The same is true if a severe laryngeal affection develops, or otitis or nephritis. Nothing seems to us a greater mistake than to attempt to establish a scheme for the treatment of typhoid fever by baths that shall be always applicable. Here, if anywhere, the only correct way is to treat each individual case according to its special symptoms and circumstances."

Brand himself modifies the bath and states that he always uses warmer baths for twenty-four hours if the patient has been ill as long as four days, and his enthusiastic follower Baruch tells us that like all agents that are powerful for good this method may produce irreparable damage (Baruch, p. 42). The depressing effect of the bath has been noticed by Liebermeister, who considers a high degree of cardiac weakness an impor-

tant contraindication. He also points out that some patients cannot bear a sufficient repetition of them, and that other contraindications may exist to their use.

Osler also tells us that the baths have often been changed to cold sponges on account of profound weakness, tenderness and swelling of abdomen, signs of perforation, and because of the active protestation of the patient. Out of 356 cases only 299 were bathed, showing that in Osler's view a fairly large proportion of cases are not suited to the bath.

Finally, the patient must be strong enough to react and rally from the bath. As we shall show, all the good effects come from reaction, and Baruch points out that the bath which is of benefit in the first week may in the third prove a fatal depressant (p. 62), and a very feeble patient in the first or second week is quite apt to fail to react.

Loomis has well said: "There is no remedial agent which requires greater care and judgment in its use than the cold bath, yet doubtless, when judiciously employed, the lives of many typhoid patients may be saved, and it is equally certain that when injudiciously employed many lives may be destroyed. The general condition of the patient and the stage of the fever must be considered; also the effects of the first few baths must be carefully noted. Should a patient's temperature range at 104° or 105° F., it is no positive indication for the resort to a cold bath, or that a cold bath is the best agent to be employed for its reduction. If the patient after the second or third bath is more quiet, has less delirium (if delirium previously existed), if his breathing becomes easy and natural, if the heart's action is more regular and forcible, and he falls asleep and perspires, there can be no question in regard to the beneficial effects of the bath. If, on the other hand, the bath is followed by feebler heart's action, by dusky cheeks, by rapid respiration, and by coldness of the extremities, from which condition the patient rallies slowly and imperfectly, it is certain that, however high the temperature may range, harm will be done by continuing the baths. When the extremities are cold, or there is profuse hemorrhage from the bowels, or when from any cause there is great feebleness of the heart's action, and especially in the case of aged persons, cold baths are contraindicated."

A large number of other authorities might be named, but we may quote Nothnagel, who asserts, that when there is cardiac feebleness

along with fever, and especially when profuse diarrhea is present, cold baths should not be used.

These quotations and the reasons given show that it is unwise and unnecessary to bathe in a tub every case of typhoid fever. This treatment has its limitations just as all others have theirs.

It is said by the bath advocates that if mild cases are not bathed they may become grave afterwards, but if this is a valid excuse then we should bathe patients with a practically normal temperature or one below that in which the bath is recommended. Personally we cannot believe in this view. On the other hand, we believe that in cases with little fever the good nursing, massage, proper feeding, sponging and care will be adequate.

We come then to a consideration of the questions, How is the good accomplished? and second, Cannot some modification of the present plan be adopted capable of attaining the same ends without the suffering of the patient and the immense labor involved, and without some of the very serious drawbacks now found associated with it?

It seems to be universally conceded that in moderately severe cases of typhoid fever the reduction of the temperature is a comparatively unimportant effect of the bath, and in the cases of marked and severe febrile movement it is of great advantage over and above the apyretic influence. In other words, it is confessed that the cold bath in typhoid fever possesses an influence of great importance upon the general system far in excess of its antipyretic effects.

It is true that Liebermeister many years ago expressed a belief that the cold bath did good solely by lowering temperature, but at that time the effects of the bath on leucocytosis, oxidation and the true influence of massage were not known, and his belief that the nervous symptoms are chiefly the result of the fever is no longer tenable and is strongly combated by Strümpel and others. To use the words of Dr. Simon Baruch, the idea that high temperature is the chief determining cause of fatality in typhoid fever must be abandoned (Baruch, p. 110).<sup>\*</sup> Further than this, the cold bath does not materially modify the whole body temperature, for as Baruch (p. 59) states in italics, "the fact is that the colder the bath the less intense its power of reducing internal temperature."

<sup>\*</sup>Baruch also says whoever expects to throttle the fever by the bath will be disappointed.

He has often seen the mouth temperature after a bath of 65° in typhoid fever reduced to normal while the rectal temperature was two degrees above normal. This is also stated by Liebermeister (*Handbuch der Path. und Therapie des Fiebers*, p. 102).

To any one who has studied the general subject of hydrotherapy it is evident that the cold bath exercises the same effect upon the blood-vessels that constant exercise of function always produces, namely, an increase in normal tone and ability to perform normal work. The blood-vessels are in one respect like rubber tubes, namely, they remain elastic as long as they are frequently exercised and become brittle as soon as they lie idle. The cold bath therefore improves vascular tone, and the result of this is a decreased tendency to stasis of blood and lymph in the tissues. Further than this, the peripheral blood-vessels being first contracted by cold are emptied as the central ones are filled, and then as the reaction takes place the flow is reversed, as it were, and the peripheral vessels are flushed by an excess of blood which cools the body by bringing hot blood to the surface and brings to the emunctory portions of the skin effete material for elimination. Finally, when the first shock and rebound of a bath is past the circulation settles back to a normal equilibrium, with the result that anemic areas have been supplied with blood, congested areas relieved, toxic matter removed from contact with vital cells and carried to the eliminative organs; with the improved circulatory state these are active in their eliminative function. Further than this, by this means perfect oxidation of tissue takes place and probably oxidation of the toxins of the disease ensue. Liebermeister, Röhrig and Zuntz have shown that the use of cold externally increases oxidation in the body so that a large amount of oxygen is taken up and more CO<sub>2</sub> is eliminated.

So far then we have a lowered temperature, an improved circulation, an elimination of toxic matters, and an improved nervous tone by removal of the fever and the poison. There is still another function performed by the cold bath, namely, an increased leucocytosis, as shown by the studies of Winternitz. This investigator has shown that the bath, and indeed all cold applications to the entire surface, greatly increases the number of leucocytes and the percentage of hemoglobin; and Thayer of Baltimore has confirmed these observations, finding in typhoid fever in particular that the number of leucocytes is in-

creased from two to nearly fourfold by this means. It would seem probable from Thayer's studies that this increase is an actual one and not solely due to a dispersing of the leucocytes from certain areas out into the general circulation. So, too, Jacquet of Basel found that the red blood cells in the general circulation may be raised about 500,000 in febrile cases by the cold bath. Thermes has reached like results.

Again, no bath in typhoid is properly given if active rubbing of the body is not resorted to while the patient is in the bath. This massage aids the effect of the cold shock most efficiently, possesses all the benefits of ordinary massage, and also greatly increases leucocytosis or leucocytic activity.

There is not space for any details in further support of these assertions; those familiar with the minute and general effect of massage know them well. J. K. Mitchell has shown that massage increases the number of the red cells and adds to their hemoglobin value both in health and in anemia.

Having indicated some of the chief methods by which the cold bath does good, we come to the second proposition, namely, Cannot some equally effective method be carried out, less harassing and exhausting to the patient and devoid of the manifest disadvantages of the bath? We admit that it is not possible for us to present an array of statistics in support of the following suggestions, because it takes a long period of time to collect an array equal to those of the cold bath and a hospital service unusually rich in typhoid cases. One of us (Dr. Hare) has used cold sponging in a more or less active form for the past ten years in his hospital wards whenever it was needed, and has rarely if ever used the bath. His results in St. Agnes and the Jefferson Hospitals suggest that the following rules be laid down for the treatment of typhoid fever cases:

1. When admitted early in the disease, with constipation or moderate diarrhea, the physician should give a full dose of calomel in divided doses in order to stimulate the liver and antisepticize the bowel with bile.

2. Control the fever when it reaches 102° F. by sponging. The patient being stripped and laid on a rubber sheet or blanket over such a sheet, he is to be sponged with water adapted in its temperature to his needs, and it is to be remembered the rapid application of a low temperature is more refreshing than the prolonged application of a higher temperature (Baruch). The chief advantage of

cold sponge lies in the shock and reaction. This is better obtained by the use of ice sponging than by the bath. The patient's surface is always bright red in ice sponging, often blue in the bath, and that the fever is not the chief danger in the case renders the fact that as great a reduction from the sponge is not reached as from the bath of little importance except in hyperpyrexia.

Shattuck tells us that he has found no marked or constant difference in the antipyretic value of cold sponging at 60° for 20 minutes, the cold pack at 60° for 20 minutes, or the cold bath at 70° for 10 to 15 minutes.

Finally, if this does not bring the temperature down to 100.5° or 101° in twenty minutes resort should be had to the tub.

It is essential when the sponging is used that more of it be applied to the back than the front of the body, for at the back the great muscles and thick skin retain the heat as a reservoir, which is not cooled if only the front of the body is sponged. Further, the posterior surfaces are the ones apt to be congested and sore from the dorsal decubitus and therefore need the stimulant effect of the bath, as do the kidneys and other deeply situated organs. That this treatment is of value is shown by the marked redness of the skin, the improvement of the circulation and respiration, and the cleared mind. That it increases leucocytosis is proved by the following studies made in my wards by Dr. Holder, my colaborer in this paper.\*

3. It is advisable not only to use friction in a light form, but to use moderately active massage with the same objects in view as when the rest cure is undertaken, for the proper treatment of typhoid is a modified rest cure. We are firmly convinced that by this means bed-sores, local congestions and effusions, edematous swellings, peripheral nerve pains and muscular feebleness will be largely decreased, and Pospischl has shown that mechanical irritation of the skin is capable of increasing heat loss ninety-five per cent.

4. In nearly all cases give more nourishment than the average typhoid patient has usually had in the past. Attention has recently been forcibly called to this necessity by Shattuck and by one of us in the editorial pages of the THERAPEUTIC GAZETTE. With the exception of broths (which are culture media for the bacillus of typhoid) and meats, almost any article easy of digestion should be allowed, as one or two or more lightly boiled eggs, corn-starch, arrowroot, etc.

5. Use stimulants in carefully graduated doses whenever the circulation needs them, particularly alcohol. Even the cold bath enthusiasts give whiskey to overcome the depression they often produce. Beyond these directions each case should be treated for the symptoms which arise from time to time. Let the physician be a watchman constantly and a therapist or hydrotherapist only as necessity arises.

#### BLOOD COUNTS IN ENTERIC FEVER.†

Case	Hemoglobin.	Before sponging.		After sponging.		Hemoglobin.
		Red blood cells.	White blood cells.	Red blood cells.	White blood cells.	
No. 1.....	60 per cent.	4,800,000	7,000	5,200,000	14,600	70 per cent.
No. 2.....	62 per cent.	4,600,000	9,000	4,600,000	11,000	80 per cent.
No. 3.....	80 per cent.	5,200,000	11,000	5,400,000	63,000	87 per cent.
No. 4.....	65 per cent.	4,500,000	7,300	4,800,000	23,000	65 per cent.
No. 5.....	55 per cent.	4,200,000	6,000	4,700,000	6,000	58 per cent.

† Technique: Thoma-Zeiss apparatus with Toisson's solution. For red blood cells from 32 to 96 squares were counted. For white cells one platform with a "cut-off," making in all 1200 squares to each count. Hemoglobin estimated by von Fleischl's hemometer. This is from three (3) separate counts at various times.

A differential count with Ehrlich's triple stain showed slight changes, such as Thayer found, in the varieties of white cells. These changes are not constant nor are they great enough to be of much value.

\* As an illustration of the fact that we have no statistics giving a fair report of the effect of the moderate and proper use of cold in fever aside from the cold bath, we may cite an instance named by a recent writer. A male of eighteen received baths during the second week of an attack of typhoid fever, and was so seriously depressed by them that a so-called "cold pack" was used. This "cold pack" consisted, we are told, in wrapping a patient in a cold wet sheet and then wrapping him in a blanket for an hour. If there be any fever present such a pack in a very few moments becomes not a means of materially reducing fever, but a hot Russian bath, and one of us

knows of a case in this city in which a hyperpyretic patient was so treated and speedily died. The case quoted from another writer is cited by him as one which shows the comparative effects of cold bathing and cold packs, although the former were used in the second week and the latter in the third, and although the cold pack as described is not an antipyretic measure of any moment. This is not a comparison between cold bathing and cold sponging, yet one reading his text would get the impression that all other methods of reducing temperature than plunging in typhoid fever were inefficient.

Finally, let us state that the object of this paper is not that of the iconoclast, nor that of one desirous of urging upon the profession any definite routine plan of treatment. It is an endeavor to determine the exact value of a well tried plan, to point out the fact that a rigid routine is inadvisable, and to suggest that the cold bath itself is perhaps equivalent to using an engine when in some cases at least hand power will equally well spin out the thread of life.

***INTRAVENOUS INJECTIONS: WITH THE REPORT OF FIVE CASES IN WHICH THE SALINE SOLUTION WAS SUCCESSFULLY USED IN COMBATING SHOCK AND HEMORRHAGE.\****

By GEORGE W. SPENCER, M.D.,

Demonstrator of Surgery, Jefferson Medical College, Philadelphia.

Having been asked by the President of this Society to read a paper, I have selected a subject which is at present receiving the attention of the medical profession. Owing to the critical nature of the cases which call for intravenous injection of saline solution and the suddenness with which the call is liable to come, the general practitioner as well as the surgeon should familiarize himself with its usefulness and the technique of its administration.

The introduction of fluids into the vascular system of an individual is by no means a new procedure. It is an exceedingly old operation and was performed in ancient times. Ovid, in his *Metamorphoses*, speaks of blood being taken from young healthy men and mixed with vegetable juices, then injected into the veins of old men who longed to renew their youth.

In 1665 (Reference Handbook of the Medical Sciences, vol. vii, p. 214) Lower, of Oxford, performed the operation of transfusion with success. He bled animals to a condition of syncope and resuscitated them by injections of blood from other animals. Denis, of Paris, followed Lower in these experiments. He transfused a patient who had been bled and purged for fever. Ten ounces of lamb's blood was injected and the patient recovered. Subsequently he was called to an insane patient who had been bled and purged without changing the mental condition. He injected nine ounces of calf's

blood, and recovery from the mental disturbance was the result. Three months later the mental trouble returned, and Denis attempted to operate again, but on opening the vein in the patient's arm found that no blood flowed. He did not finish the operation and his patient died. The wife charged the physician with killing her husband, and the latter retaliated by saying that she had administered poison to him. The case created considerable excitement in Paris, the operation fell into discredit, and a law was finally passed forbidding its performance.

In 1665 two German surgeons, named Kaufmann and Purmann, claimed to have cured a leper by the repeated injections of lamb's blood. During many years blood from animals was occasionally injected into the vascular system of the human patient to meet certain demands, but this maneuver was looked upon with disfavor, as many believed that the blood of calves and other animals contained particles of various kinds necessary for the development of such peculiar tissues as horns, etc., belonging to these animals, and that consequently these elements would prove deleterious when in the vascular system of the human patient.

There seems, according to the old writers, to have been considerable diversity of opinion as to what becomes of the blood-corpuscles when taken from an animal of a different kind. Marfels and Moleschott (quoted by Hamilton, Text-book of Pathology, vol. i, p. 474) recognized the blood-corpuscles of the sheep in the circulation of the dog months after they had been transfused. It is said that between animals closely related blood can be interchanged with impunity; for instance, the blood of the calf for that of the lamb, and horse's blood for that of the ass, but in case of man it has been found that it is safe to transfuse only from one individual to another.

At the present day there is scarcely any difference of opinion with regard to the use of blood from the lower animals; it is regarded as dangerous, and it is seldom or never employed. The transfusion of milk had at one time many advocates. Dr. Joseph W. Howe, of Brooklyn (Reference Handbook of the Medical Sciences, vol. viii, p. 221), in speaking of his experiments upon dogs with the intravenous injection of milk, says that when he had bled seven dogs to a state of syncope, milk was injected and not a single recovery took place. Two dogs were bled in a similar manner, no milk was injected,

\*Read before the W. W. Keen Surgical Society, Jan. 8, 1898.

and recovery occurred in each case. The only conclusion that can be drawn from this is that the milk killed the dogs. Dr. Schafer, of New York (Jacobson's Surgery, 3d edition, p. 90), found that the injection of milk, after dogs had been reduced by bleeding to an almost lifeless condition, caused a temporary rise in the blood-pressure, but no permanent benefit. On post-mortem examination the blood-corpuscles were found to be disintegrated and the blood swarming with bacteria.

After it had become evident that the blood of animals would not functionate properly in man and that milk in the hands of many proved unsatisfactory, it became a universal practise to use human blood for transfusing purposes, and for years it was a question whether human blood should be introduced in its natural state, or be deprived of its fibrin before being introduced.

The old as well as the recent literature on the subject tells us that transfusion of pure blood is followed sometimes by capillary thrombosis. One great trouble with defibrinated blood is the uncertainty of its action; it is sometimes harmless, but at other times highly dangerous. It has been suggested that some saline solution having the power of delaying coagulation—*i.e.*, sodium phosphate—should be added to blood before it is introduced. Dr. W. Hunter (*British Medical Journal*, 1889, vol. ii, p. 305) condemns its use. He is of the opinion that the use of a three-fourths per cent. solution of sodium phosphate will cause red corpuscles to break up and disappear in twenty-four hours, and that the use of this salt with the blood will not prevent the occurrence of capillary thrombosis.

The great difficulty which is often experienced in obtaining human blood for transfusion, and its want of advantage over the ordinary saline solution in the majority of cases, to say nothing of its dangers, has led the operators of to-day to use the saline solution exclusively.

Before going into the question of the advantages of the normal saline solution over the previously recommended fluids for the intravenous injections, it will be well for us to look into the elements of the blood that are essential to life and how these elements are affected by introducing other substances into their midst. We know that vital activity of all kinds—respiratory, nervo-muscular, etc.—necessitates a constant and free supply of oxygen, and this want is filled by the circulating blood carrying the red corpuscles

laden with the indispensable element. We have been taught that the hemoglobin is that part of the blood which absorbs and gives up the greatest part of the oxygen, and that it is to their hemoglobin that the red corpuscles owe their function of being oxygen carriers. When we study the circulation and the respiration we see that the healthy corpuscles absorb oxygen during inspiration, and while these corpuscles are passing through the capillaries they give up the oxygen, which combines with carbon to form carbon dioxide or carbonic acid; this in turn is carried by the corpuscles to the lungs, where it is exhaled. Any condition which arrests the activity of the corpuscles will cause death by allowing the accumulation of carbonic acid. From the above it is a just inference that the corpuscles must not only be capable of functioning properly, but must be in circulation at all times and under all circumstances. Besides corpuscles and their hemoglobin, which we consider to be a source of power, the human blood contains water, fibrin, albumen, fats, and salts. As fibrin exists in such small quantities in the blood, some distinguished physiologists think it is a product of the activity of the tissues, and in normal circumstances is destroyed as rapidly as it is formed, being burnt up by the oxygen and converted into excrementitious material (Chapman). There must be something in this view, as blood, when it has been whipped and deprived of its fibrin, seems to accomplish as much as pure blood, when injected into the vascular system of another animal. Albumen, salts and fats are supposed to furnish materials for the tissue for repair, and while they are really essential to life and comfort in the long run, we can conceive of no immediate condition in which the vital forces are dependent upon them.

The above statements show the fallacy of using milk for transfusing purposes in cases where there has been a sudden loss of blood. Next to water, common salt is the most important of the proximate principles of the blood. It not only gives to the blood its alkalinity, but enters freely into the process of osmosis, promotes absorption, and aids in preventing dissolution of the corpuscles. Since water forms three-fourths of the blood, it must necessarily play an important part in keeping up the volume of the blood.

After severe operations in which there has been considerable blood lost, there is always a great fall in the blood-pressure, and death sometimes ensues on account of failure of

circulation due to the rapid fall in the pressure. In health the blood-pressure is dependent mainly upon peripheral resistance, and this in turn depends upon the action of the vasomotor nerves.

Whatever may be the cause of lowering or raising the blood-pressure, it is certain that the pressure is lowered in cases of severe hemorrhage, and is raised when fluid is injected to replace the lost blood. Indeed, the blood-pressure is influenced by the intravenous injection of fluids in patients who are not suffering from shock or loss of blood, as I will show presently.

Dr. Woolridge, of London (*Lancet*, 1891, vol. ii, p. 626), shortly before his death, had been making experiments on transfusion in animals, by means of which he was able to show that after an animal had sustained a loss of blood sufficient to terminate its life, there was left in the blood vascular system enough corpuscles to sustain life, if sufficient fluid be added to keep them in circulation. So strong was Dr. Woolridge's belief in the value of saline solution that he used to tell the students in his lectures on physiology, "No person should die of hemorrhage."

Reconsidering, it seems evident that the elements necessary to sustain life in a person previously healthy who has lost considerable blood are healthy corpuscles, which must be suspended in a fluid the character of which is harmless to the corpuscles and the pressure of which must be sufficient to carry these corpuscles from the lungs through the capillaries and back to the lungs. Since the question has resolved itself into one of corpuscles and fluid, and experiments have shown that after a severe hemorrhage a sufficient number of corpuscles remain in the blood vascular system to maintain life if only enough fluid be introduced to keep them in circulation, the question which remains is, What fluid would prove to be the best? We are inclined to believe that the nutritive value of blood, whether pure or defibrinated, for transfusing purposes is very small, that its real value depends upon its physical properties, and these are in no manner greater than an equal quantity of any fluid which will raise the intravenous pressure and not interfere with the activity of the corpuscles. Quantity and not quality seems to be the chief cry of the corpuscles after severe hemorrhage. In view of this fact the question may arise in the minds of some why ordinary water would not suffice. In an emergency the intravenous injection of ordinary water

has been followed by results as successful as any ever obtained after transfusion of blood (Coates, quoted by W. Hunter, *British Medical Journal*, vol. ii, p. 309). Now that it is known that ordinary water can be used for intravenous injection, we ask ourselves if this can in any way be modified. Next to water common salt is the most important of the proximate principles of the blood, absorption and osmosis being influenced by it. If it had no other action than that of assisting the corpuscles to absorb oxygen in a critical period, it would be justifiable to use it; but more than this, it is claimed that the existence of the corpuscles partly depends on the presence of sodium chloride, which absorbing any superfluous water prevents their dissolution. The experimental research on intravenous injection of various solutions (by MM. Bosc and Vedel, *Gazette des Hôpitaux*, 1896, p. 938) is interesting. The authors experimented with the following solutions: distilled water, ordinary water, simple saline (chloride of sodium) solutions, and the so-called artificial serum, sodium chloride and sulphate of sodium (equal parts of a strength of 7 in 1000). Their conclusions are as follows: Distilled water is noxious even in small doses and ought not to be injected alone in the veins. Ordinary water is, on the contrary, not toxic. Its destructive effects on the red corpuscles are less marked than those produced by distilled water, and in emergency it may be injected intravenously by itself. Simple sodium chloride solution is quite innocuous so long as the quantity of salt does not exceed three times the quantity of the sodium chloride contained normally in the blood. The physiological value of the artificial serum solution is not superior to that of the simple saline solution, and simple salt solution 7 per 1000 is the most convenient for intravenous injection.

Dr. William Hunter, in his admirable address on transfusion, delivered at the Royal College of Surgeons, London (*British Medical Journal*, vol. ii, 1889), said: "Any advantage that transfusion of red corpuscles may have over simple saline injections is counterbalanced by the dangers attending the simultaneous injection of the white corpuscles. In the case of defibrinated blood, the latter so preponderate that the transfusion of defibrinated blood is an operation not only dangerous in itself, but one whose practical value by no means serves to compensate for the additional risks run in carrying it out. Under no circumstances is transfusion of

milk or of other mixtures possessing what are supposed to be nutritive properties ever indicated. They possess no value not possessed by an equal bulk of saline solution." Dr. Hunter also said his experiments upon animals show that the recovery after intravenous injection of the saline solution is remarkably rapid. The time required for the return of the red corpuscles to their original number after loss of blood, without subsequent transfusion of blood, varies from two to three weeks. With subsequent injection of simple saline solution it is the same; whereas with subsequent transfusion of blood complete recovery is delayed a week or more. Further, what is perhaps more striking and certainly is of more importance, is the fact that during the subsequent recovery the animals generally appear to be in better health after intravenous injection of the saline solution than after transfusion of blood. The intravenous injection of the saline solution is, then, to be recommended above all other operations in cases where there is a fall of blood-pressure due to the excessive loss of blood. Its use is also indicated during severe operations as a preventive of traumatic anemia.

There have been many theories advanced in regard to the pathology of shock. Some are of the opinion that the great mass of blood, owing to vasomotor disturbances, stagnates in the abdominal vessels, but little of this fluid getting to the vital centers. Others adopt the theory of reflex paralysis of the vasomotor nerves, holding that at first there is contraction and subsequently general dilatation of the blood-vessels, and that the heart is unable to force the small amount of blood through the empty vessels. Its own muscles are insufficiently supplied with stimulus, and it gradually stops beating. If either of these theories be accepted, or if we pin our faith to the theory that shock is a sort of heart failure due to a temporary paresis of the muscles of the heart, the indications for treatment in each case are the same, and the whole problem rests upon the inability of the heart to force the blood through the blood-vessels and at the same time to furnish proper nutrition to its own substance. Experiments upon animals prove the importance of the fluid in the cavities and in the heart substance itself. If the heart of a frog be taken entirely out and emptied of blood, the beating will stop; but if a few drops of warm water or blood be introduced into the ventricle the contraction will recommence. Even frag-

ments of the heart will contract and dilate if a few drops of warm water be applied. While the presence of fluid, whether blood or warm water, within the heart cavities will stimulate the muscular fibers and cause contractions, we know that contractions are influenced by the presence of blood in the heart substance itself.

With each ventricular systole blood is forced into the aorta and the blood that the coronary vessels receive is delivered by these vessels into the substance of the heart. The importance of blood flowing through the coronary system of vessels is evident when it is known that if the coronary arteries of an animal be ligated the heart will almost immediately stop beating. Since the coronary arteries arise from the aorta near its commencement and immediately above the semilunar valves, they must necessarily be the first vessels in the body to receive a portion of the heart's contents. Accordingly the heart muscles must be the first muscles in the body to receive nourishment, and nourishment means muscular force. In the first theory of shock the blood stagnates in the abdominal vessels, and naturally the heart muscles are forced to feebly contract, practically, on space. The blood, and particularly the carbonic acid in the venous blood which is known to stimulate the inner wall of the heart and cause contractions of the muscles to a certain degree, cannot reach the heart in sufficient amounts to do good. As the general circulation is depressed the coronary circulation, which is a source of power in itself, is bound to suffer in proportion. In the second theory the conditions are about the same. The last theory shows blood to be in the heart cavities, but the contractions are not of sufficient force to drive it out with the proper vigor.

Physiologists tell us that the flow of blood in the veins is essentially due to the contractile force of the heart. Experiments, as we have just seen, show us that vigorous contractions of the heart can be produced by introducing a warm solution into the ventricle. With a cannula in the median basilic vein, or if necessary in extreme cases in the external jugular, a warm saline solution can be forced into the right side of the heart. The presence of the solution will not only give the fluttering heart something to contract upon, but will stimulate the inner wall and cause contractions. A few vigorous contractions should be a factor in starting the great mass of blood that had settled in

the abdominal vessels. With the return of the venous blood to the right side of the heart will come the carbonic acid, which is known to be a powerful stimulus to the inner wall. With the return of the arterial blood, the coronary vessels will receive their share and give to the heart the nutritive materials out of which the muscular or contractile force of the heart is developed. No doubt in many cases of shock death occurs from the want of a few vigorous contractions of the heart muscles. Some may take the ground that the changes in the vascular system in shock are secondary to the action of the sympathetic nervous system. I am treating the effect rather than the cause.

If the condition in regard to the circulation in shock be due to a general depression of the nervous system, or if the weak action of the heart be due to a vasomotor paralysis, or if we accept the theory that overirritation causes fatigue of the nerve centers and this is manifested by reflex paralysis, our object in each case is the same, namely, to support the heart's action the best we can until the nervous system as a whole or a part recovers itself, and when this happens the individual filaments as well as the centers will receive Nature's stimulus, the blood.

It is well enough for some to treat shock with such drugs as are known to exert their chief influence on the nervous and vascular systems, such as strychnine, digitalis, etc., but it should be remembered that these drugs are only useful in cases where the vitality of the system is in such a condition that absorption can take place. If the blood circulates freely in the tissues, absorption is active; but if the circulation is depressed, absorption is slow.

In cases of severe hemorrhage, collapse or shock the subcutaneous tissues are deprived of blood to such an extent that absorption cannot take place. So the repeated doses of powerful drugs which have been introduced into the subcutaneous tissue from time to time during collapse, shock, or the exhaustion from hemorrhage, cannot be absorbed until the vital functions of the patient are restored; then these drugs, suddenly absorbed and acting together, may poison the patient.

In December, 1893, Dr. William Wells and I were called to see a young woman who had just given birth to a large child and was having a fearful post-partum hemorrhage. We induced uterine contractions by injecting hot water and packing, after which we directed our attention to her exhausted state,

as she had lost so much blood that she was nearly dead. There was in the patient's room a bottle which contained a solution of strychnine; five minims of this solution contained one-twentieth of a grain of the alkaloid. A metal barrel hypodermic syringe, the capacity of which was thirty minims, was filled from this bottle and handed to me when I asked for one-twentieth of a grain of strychnine in solution. The contents of the syringe was injected into the patient's arm. This injection had no effect, and half an hour from the time it was given we were informed that the syringe instead of containing one-twentieth of a grain of strychnine dissolved in thirty minims of water, each five minims contained one-twentieth of a grain. It was evident that the patient had received at one injection three-tenths of a grain of strychnine without producing any perceptible changes in the respiratory, circulatory or nervous system. We attributed our good luck to the non-absorbing qualities of the tissues, and for fear of getting poisonous effects of the drug when reaction occurred, thirty grains of bromide potassium and fifteen grains of chloral were given by the mouth, and twenty minutes later a similar dose of the same drugs was given by the rectum. The patient recovered and was living and in good health one year after the confinement. The solution used in this case was prepared at the Jefferson Hospital drug dispensary, and I have every reason to believe it was fresh and capable of producing positive effects under favorable circumstances.

I mention this case to show that in cases of excessive hemorrhage the vitality of the patient is so reduced that drugs cannot be absorbed.

If absorption cannot take place when one is bleeding from his vessels, I cannot see how it will take place when one is bleeding into his vessels, as in case of severe shock. In both conditions the circulation is so interfered with that the tissues do not receive enough blood to even start absorption.

Drugs by the rectum, drugs by the mouth and drugs by the hypodermic method have no place in extreme shock. Paget says: "There is, perhaps, no case in the management of which the courage to do little is more needed than in shock. Great energy of treatment may do great mischief." Rest, external heat and the intravenous injection of a warm solution seem to meet the indications in extreme shock. When the signs of

reaction have well appeared, the use of saline solutions must be discontinued; then comes the time for the use of strychnine, digitalis, etc. The quantity of the saline solution to be injected varies according to the age, the amount of blood lost in cases of hemorrhage, and the reaction signs in cases of shock and collapse. In cases where there has been considerable blood lost the amount should be greater than in cases of collapse or shock. The quantity ranges from a few ounces up to three or four quarts. The chief guides in any case are the return of the pulse, with increase in volume and diminution in rate (for instance, a fall from 140 to 90 or 100), return of color, facial expression, and consciousness. The temperature of the solution should be kept at about 100° while injecting. A convenient way of handling the solution is as follows: Have three quarts of a cooled boiled solution containing twelve drachms of salt. When the time arrives to administer the saline solution, take a small quantity of the above solution and add to it an equal amount of boiling water; the solution will then be ready to inject. The fluid should be forced in gently and the pulse should be carefully watched for fear of overloading the vessels. Strict attention should be continuously given to the pulse and respiration in cases of shock and collapse treated by this method.

Where this treatment has extended over a considerable period and the quantity injected has been large, the condition of the bladder should be looked after. The technique of the operation is simple.

While any large superficial vein could be used to receive the solution, the median basilic has in a large majority of cases been selected. In some instances, according to the collapsed condition of this vein, it cannot be identified. The outline of the vein can be made prominent if a moderately tight bandage be applied around the arm just above the elbow and then have flexion and extension performed at the wrist. These movements will increase the blood-flow and distend the wall of the vein.

After the parts have been thoroughly cleansed and the forearm placed in a position of supination, an incision one inch in length should be made over the vein at the bend of the elbow and carried through the skin and superficial fascia. This incision will bring into view a layer of fat, which is very often seen and very rarely spoken of in our text-books. In all of my cases this layer of

fat was present. With a blunt instrument the fat can be torn through and the vein exposed. Three catgut ligatures should be placed under the vein, and one of the ligatures should be drawn well down into the lower angle of the wound and immediately tied. An opening just large enough to receive the cannula should be made in the vein wall above the point where the ligature was tied. Into this opening the end of the cannula is introduced. A second ligature is now tied around that portion of the vein which includes the end of the cannula. This ligature not only holds the instrument in place, but prevents the entrance of air. After the required amount has been injected, the third ligature should be tied in the extreme upper angle of the wound above the end of the cannula. The cannula can now be taken from the vein, or that part of the vein between the upper and lower ligatures can be excised, removing the excised portion of the vein with the cannula in situation. The wound needs no drainage, is closed with several silkworm-gut sutures, and dressed with aseptic dressings.

In extreme cases of shock, hemorrhage or collapse the superficial veins may be so empty that they cannot be made prominent by the bandage and wrist movements. If the vein desired is not readily found, a transverse incision should be made in the subcutaneous fat across the line of the vein. This incision will divide the vein and the collapsed ends can be recognized. The lower end should be ligated and the upper end should be treated as in the above operation. The instrument used in conveying the solution must be as clean and as simple as possible. When there is no special instrument at hand for introducing this solution by the intravenous method, an ordinary glass or rubber syringe, with a piece of india-rubber tubing attached to its nozzle and a cannula attached to the other end of the tubing, will suffice. The cannula can be of glass or metal. A small goose-quill would answer equally well in emergency cases. One of the most convenient and safest instruments for this purpose is Collin's transfusion apparatus. It was used extensively for transfusing blood during the French and German wars and gives perfect satisfaction. This apparatus was used with success in the cases that I will speak of presently. Collin's instrument consists of a reservoir or basin which is funnel-shaped and holds about one pint. To the bottom of this basin is attached a glass syringe which holds half an

ounce and works like any other ordinary syringe. To the lower angle of this syringe is attached a rubber tube with a cannula at its end. The entrance to this tube is guarded by a hollow ball-valve made of aluminum, which completely excludes the air. The basin is filled with the solution, the piston is drawn back, and the barrel of the syringe becomes filled; the piston is then pushed, which drives the ball-valve up and allows the fluid to go through the tubing and cannula into the vein. After one syringe-ful is thus delivered the ball drops back over the entrance of the tube. To be sure that there is no air in the tubing or cannula, one syringe-ful should be emptied before the cannula is introduced. After the first syringe-ful is delivered it is impossible for air to enter. The basin should never be less than one-third full, and the solution in the basin can be kept at the proper temperature by constantly adding small quantities of the saline solution, hot or cold, according to the temperature of the fluid in the basin. While the presence of air in the vessels in small quantities has been shown by experiments not to be injurious, it is best to avoid it if possible.

I am inclined to think that the intravenous method of introducing the saline solution into the venous system would be used more freely if it were not for the disturbances that the air in the vessels is claimed to cause. And why should we fear the small amount that is liable to get in during this operation, when we are told by Hare that death only occurs when a pint or more has been introduced into the vascular circulation? The circulation can, no doubt, handle a small amount of air without fatal results. I have seen the internal and external jugulars and the axillary veins torn without any perceptible changes in the circulation, and I am sure in each case considerably more air gained entrance than could possibly get in during the operation for intravenous injection.

My experience with the saline solution used intravenously is limited to only four cases, though I have seen it used in other cases with good results.

Cerebral surgery is almost always accompanied by severe shock, particularly when there has been considerable blood lost, as happens when brain tissue is being removed. Profound shock is sometimes seen to follow exploratory operations upon the brain, even when nothing more has been done than exposing the dura.

While we are ready to admit that the shock caused by the removal of a limb at a joint is claimed by some to be modified if a portion of the limb had some time previously been removed, we know that no patient can have his clavicle resected, subclavian vessels ligated, brachial plexus incised, scapula, portion of the clavicle and arm all removed at one operation without considerable hemorrhage and profound shock. It goes without saying that an extensive resection of the lung tissue for disturbances caused by traumatism is followed by a hemorrhage which kills in the vast majority of cases.

The following cases, with the exception of the first, will serve to demonstrate the usefulness of the saline solution used intravenously for counteracting the effects of operations which ordinarily are accompanied by severe shock. While the first case that I will speak of throws no light on the use of the saline solution in cases of shock and hemorrhage, it shows us the effect this solution has when introduced into the vein of a person who has normal secretions, normal blood-pressure, normal temperature, and normal respirations. I believe it is the first case on record where the saline solution has been introduced into the circulation of a human being in whom the vital functions seemed in every respect normal.

CASE I.—Joseph L., aged forty-eight, was admitted to the surgical wards of the Jefferson Medical College Hospital, July 28, 1896. Diagnosis: carcinoma of the tongue with extensive glandular involvement. The floor and sides of the mouth were so infiltrated that it was impossible to make a careful examination, so it was decided to give the patient ether, make a thorough examination, and if possible remove the diseased tissue. From the condition of affairs it seemed certain that the operation would be long and bloody. In view of this fact Professor Hearn asked me to be ready to administer the saline solution intravenously in case it was needed. On August 1, 1896, the patient was anesthetized, and while the mouth was being cleaned I exposed the median basilic vein and introduced into it a cannula attached to a Collin transfusion apparatus. The mouth of the patient was now forced open for examination. The tongue was found to be infiltrated throughout; it was dark, thick, and fixed. Its motion was so limited that it could not be brought forward. The disease extended to the pillars of the fauces, the soft palate, and the tonsils. The floor of the mouth, the

gums and the jaw bones were involved, also the cervical glands. After a most thorough examination, Professor Hearn concluded an operation in a condition like this would not only subject the patient to a great risk, but could not in any way prolong his life, and for this reason no operation was performed. The patient had now been under the effects of ether for fifteen minutes and he was none the worse for it, as his pulse was 81 per minute, temperature 98.6°, and respiration 20. Having everything ready for the intravenous injection of the saline solution, and thinking that no harm could befall the patient if a small amount was carefully injected, I did not hesitate to try to ascertain the effect of the saline solution in a patient whose vital organs were functioning properly. Dr. Meals, who was at this time resident surgeon to the women's surgical wards, kept his finger on the radial pulse of the left arm while I was injecting the solution into the median basilic vein of the right arm. His report was as follows:

Time.	Amount injected.	Pulse.	Respiration.
12.30 P.M. ....	None.	85	20
12.32 P.M. ....	Two ounces.	85	20
12.34 P.M. ....	Two ounces.	81 (volume increased).	20
12.36 P.M. ....	Two ounces.	79 (volume increased).	18
12.41 P.M. ....	Two ounces.	71 (volume increased).	18

The patient soon recovered from the effects of the anesthetic and passed four and a half ounces of urine (his bladder was evacuated immediately before he was anesthetized).

This case is interesting from several points of view; it shows us that eight ounces of saline solution can be introduced, within a period of nine minutes, into the blood vascular system of an individual whose vessels are already filled without perceptible evidence of engorgement. It clearly demonstrates that the vital functions are increased by the presence of the saline solution within the circulation.

From the fact that the patient passed four and a half ounces of urine one hour after he had evacuated his bladder, and forty-five minutes from the time of the first injection and thirty-six minutes from the time of the last, it is reasonable to believe that the increased blood-pressure caused the kidneys to become active, and they were endeavoring to equalize the blood-pressure by getting rid of any superfluous fluid.

The case just spoken of being the only

one in my list of five in which no operation was performed, I numbered it No. 1, so as to clear it of the operative cases, though it was the third to receive the solution. My first experience with the saline solution used intravenously was at the Orthopædic Hospital on June 5, 1896. The history is as follows:

CASE II.—H. McD., aged twenty-eight, was admitted for the first time to the above named hospital on March 16, 1893. He was suffering from epilepsy, supposed to be caused by a brain tumor. On the 3d of April Professor Keen exposed a portion of the brain for exploratory purposes; nothing unusual was visible. A grooved director was passed into the right lateral ventricle; no tumor was found. The director was then passed about two inches down and back into the brain substance. Nothing abnormal could be detected, and it was decided if any tumor existed it was deep at the base of the brain. This operation was followed by considerable relief for a time; but later the epileptic attacks returned, and the patient was brought back to the hospital. Upon his arrival the second time his symptoms and physical signs of a cerebral tumor were prominent and the patient was very weak. On the 6th of June, 1896, Professor Keen reflected the portion of the scalp that overlay the tumor; the bone had been removed at the previous operation. The opening in the skull was enlarged, and through it two ounces and one hundred and fifty grains of diseased brain tissue was removed. This was attended by a fearful hemorrhage, and the patient was rapidly sinking. I was asked to give him an intravenous solution. This was my first experience with the solution used in this manner, and the inexperience, combined with a new transfusion apparatus which was minus an important washer, produced effects which were not as prompt and as satisfactory as they might have been, though I managed by perseverance and time to get into his vein enough of the fluid to have a mild effect on the circulation. He was somewhat shocked after the operation, but soon reacted and recovered from the operation.

CASE III.—W. H. B., aged twenty-eight, was admitted to the Jefferson Hospital on July 11, 1896. Diagnosis: tumor of the brain near the cuneus. He was suffering with terrible headaches, was very weak, and hardly able to walk. There was a history of progressive loss of strength, weight, and sight. When admitted he had right lateral hemi-

anopsia and passed large quantities of urine, the amount varying from ninety to one hundred and twenty ounces in twenty-four hours. The original history of this case could not be found, and I am indebted to Dr. J. Roe for the above interesting facts connected with it. My notes of the case show that he was operated upon on August 5, 1896. After he was anesthetized his condition was somewhat alarming; the pulse was rapid and weak, 132 per minute, respiration 24 and shallow, skin cold and clammy. Professor Hearn was about to send him back to the wards without touching him with an instrument, and would have done so if his condition had not improved under the use of the saline injection. The operation lasted fifty minutes and consisted of opening the skull and exploring the brain with finger and dural separator. Nothing was found to account for the disturbances. Dr. Dengler, chief anesthetist at the hospital at the time, and Mr. Sciple, a third-year student, kindly paid particular attention to his pulse and respiration while I was injecting the solution. They furnished me with this report:

Time.	Amount injected.	Pulse.	Respiration.	Face.
1.07 P.M. . .	None.	132	24	Pale.
1.09 P.M. . .	Three ounces.	132	24	Pale.
1.15 P.M. . .		130*	24	Pale.
1.19 P.M. . .	Three ounces.	130*	24	Pale.
1.23 P.M. . .		124*	23	Pale.
1.26 P.M. . .	Three ounces.	124*	23	Pale.
1.28 P.M. . .	Three ounces.	120*	22	Pale.
1.30 P.M. . .	Three ounces.	119*	20	Pale.
1.35 P.M. . .	Three ounces.	100†	19	Little color.
1.42 P.M. . .	Three ounces.	90†	19	Fair color.

\* Volume increased. † Full.

1.51 P.M. Patient shows signs of throwing off the anesthetic.

1.51½ P.M. Cannula removed; patient in fair condition.

The patient made a rapid recovery from the operation.

I am sorry that I cannot show a complete history with the urinary report of this case, but the facts as they stand show that a person considerably shocked from disease and the anesthetic can be benefited by the introduction of a warm saline solution into the circulation. A reduction of the number of heart-beats from 132 to 90, with increased volume during a period of forty-four minutes, shows the value of administering the solution while the person is passing from shock into what would be in a little while extreme shock. Following the pulse-rate and volume in this case from the beginning of the first injection to the time the opera-

tion was completed, it substantiates what I said a few moments ago in regard to the influence of a warm solution introduced into the right side of the fluttering heart.

CASE IV.—J. M., aged twenty-eight, was admitted to the Jefferson Hospital on May 26, 1896, suffering from the effects of a recurrent carcinoma of the upper third of the right arm and shoulder. The arm had on a previous occasion been amputated at the middle third for a carcinoma, which began in the thumb and was gradually extending up the forearm. On June 3, 1896, Professor Hearn removed the entire upper extremity, including the scapula and outer two-thirds of the clavicle. The operation was preceded by resection of the clavicle and ligation of the subclavian vessels. The patient was cold, and in a perilous operation like this severe shock seemed inevitable. Dr. Gilbert, then surgical resident in the men's surgical ward, assisted me in looking out for the patient's general condition. By the external application of heat and the introduction of twenty ounces of warm saline solution into his median basilic vein, he suffered very little shock and soon recovered from the operation.

CASE V.—G. P., aged eighteen, was admitted to the Jefferson Hospital on June 17, 1897. Diagnosis: Gunshot wound of the chest. On admission his pulse was 100, respiration 32. Soon after admission he became delirious, pulse increased to 132 per minute, and his skin became cold and clammy. He showed all signs of internal hemorrhage. Accordingly, Prof. J. Chalmers DaCosta aspirated, and, finding blood, followed this by resecting three ribs, opening the pleural cavity, removing necrotic lung and pleural tissue, ligating a number of vessels in the lung, and packing with sterilized gauze. The blood that escaped through the wound in the chest was caught in a bucket, and it amounted to half a pint over a gallon. To counteract the effects of this, two quarts of the normal salt solution was used intravenously. Professor Da Costa thinks that the intravenous injection saved his patient's life. (I had nothing to do with the administration of the saline solution in this case, nevertheless I am glad to report it with my own cases, as it admirably shows the effect of this fluid in an operation on a vital organ with a considerable loss of blood.)

Dr. Lewis A. Stimson (*Medical News*, Dec. 19, 1896) reports a number of cases of pure shock which he treated with the intravenous

injection of the saline solution. Three of his cases were accident cases, and when admitted to the New York Hospital were in a condition of extreme shock. They recovered under the use of the saline solution.

*SCHUDE'S OPERATION FOR AN OLD EMPYEMA; CATHCART'S DRAINAGE; RECOVERY.\**

By W. W. KEEN, M.D.,

Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia.

J. F. S., aged twenty-four, was sent to the Jefferson Medical College Hospital by Drs. John and George Potteiger, of Hamburg, Pa., December, 1895. His family and personal history are negative, excepting that at twelve years of age he had an attack of chorea, which lasted for a year and recurred slightly a year later, but has never returned.

In April, 1895, between eight and nine months before his admission, he had a left-sided pneumonia followed by pleurisy with marked bulging of the precordial region. This was incised, and drained on May 30. A second incision was needed at a later date, and a third about the 1st of August. On admission there was no healthy breath sound over the entire left side of the chest. The left chest wall was considerably flattened, especially at the upper portion. The apex of the heart was displaced two inches to the right. Specific gravity of urine 1.032; neither albumen nor sugar.

Three sinuses still existed at the point where the incisions were made (Fig. 1). Evidently the attempt by Nature to cure by approximating the chest wall had not succeeded by reason of the rigidity of the chest wall. This, from the long-continued supuration, I deemed to be probably due as much to the thickened pleura as to the ribs.

Operation December 4, 1895. I first made an incision connecting the various sinuses and removed the diseased tissues around these apertures. An opening into the interior of the chest was found between the fifth and sixth ribs just in the nipple line. A long probe reached upward as high as the clavicle, downward to the diaphragm, and backward to the posterior wall of the chest. A long curved incision was made extending from the first incision to the scapula. The flap covered most of the side of the chest.

The incision was made directly down to the ribs, and all the soft parts external to the ribs were lifted. Beginning then at the opening into the chest cavity, by a large pair of bone pliers I divided all the tissues of the chest wall up to, but not including, the second rib, downward to the diaphragm, and at the upper and lower extremities of this incision I divided the entire thickness of the chest wall well back under the anterior edge of the scapula, and vertically between the ends of these last, thus removing the wall of the chest (except the flap) from the third to the eighth ribs inclusive. The pleura was nearly an inch thick and its cavity was filled with pus. The left lung was obliterated and bound to the inner side of the apex of the left chest; the pleuro-pericardium forming a vertical diaphragm about an inch inside the nipple line. The entire surface was curetted

FIG. 1.

and lightly packed with iodoform gauze. The flap was then sutured in position, except at an opening below for drainage. My intention in suturing the flap except a small drainage opening was to obtain its adhesion to the soft parts as far as I could. I then intended in three or four days to cut the sutures at the apex of the curve so as to get more room for drainage and packing; especially would the drainage be good when he was in the erect posture. No trouble was experienced with hemorrhage. The bone forceps apparently arrested the hemorrhage by crushing. The ribs were adherent to each other.

After the operation his temperature fell to 95.6°, but by the fourth day had gradually risen to 102.2°. On the sixth day it had

\* Read before the Surgical Section of the College of Physicians, April 9, 1897.

fallen to the normal and remained so till he was discharged.

I found, after the first few days, that the abundant suppuration in the old cavity of the pleura was not freely drained by the gauze, and accordingly I applied the apparatus of Mr. Cathcart as modified by myself (*Annals of Surgery*, February, 1896). This kept the cavity entirely free from pus.

At the time of the operation the cavity held considerably more than a quart of pus. In two weeks there had been such contraction that it held less than a pint. He was discharged on January 22, 1896. There was still a small fistulous opening, leading to a cavity holding about three ounces. By the end of February it only held two ounces, and the falling in of the flap was rapidly advancing toward cure.

The operation that I did in this case, and also in another (*Annals of Surgery*, June, 1895), is not precisely that of Schede in its details, but practically is the same, and I have therefore called it by his name, though I employed it in my first case without knowing that Schede had ever done it. His original paper will be found in the *Verhandl. d. Cong. Innere Med.*, 1890, p. 41. Schede's operation is not as well known in this country as it ought to be. Ferguson (*Journal of the American Medical Association*, Jan. 9, 1897) in reporting a case stated that in looking through American medical literature he had not been able to find any other case whatever, overlooking the first case of my own to which I have just referred. Estlander's operation (thoracoplasty) is very well known and finds a place in all the text-books. Schede's, which is a radical improvement of the same, receives bare mention in the recent systems of Park and Dennis, and is not even referred to in Mr. Treves' *System of Surgery* or in his *Operative Surgery*. The American Text-book of Surgery describes the operation quite fully.

The operation of Schede is especially applicable to very old cases in which the pleura, as in the present case, reaches the thickness of an inch or an inch and a quarter. It is very evident that mere removal of the ribs, leaving such a thickened pleura, will do no good, since the pleura is so stout and firm that it preserves the arch of the chest wall and therefore the cavity persists. Accordingly, the principle of Schede's operation is to make a flap of the soft parts down to the ribs, and then remove ribs, intercostal muscles and thickened pleura entirely. The flap,

which has been raised, is then replaced so that the skin and subcutaneous tissues lie directly on the inner side of the old thickened pleura, which should be thoroughly curetted before the flap is replaced.

FIG. 2.

The incision begins (see Fig. 2) at the level of the axilla in front, extends below to the lower border of the pleura, and then curves upward posteriorly to the level of the second rib between the scapula and spine. The entire soft parts (including the scapula) down to the ribs are then raised. All of the ribs from the second or third downwards and from the costal cartilages to the tubercles are

FIG. 3.

removed. The thickened pleura is then, in the entire extent of the wound, split, and with the intercostal muscles are removed with a strong shears. In both of my own cases I have not first resected the ribs and

then the pleura as was done by Schede, but I have divided the entire chest wall under the soft parts by a strong pair of bone pliers. If the intercostal arteries bleed they are, of course, ligated. In my own cases I did not have to ligate any of them. Apparently the crushing of the forceps jaws prevented the hemorrhage. After thorough curetting of the visceral layer of the pleura, the flap is then laid upon the lung and pleura where it usually heals *per primam*, with an immediate subsidence of the fever. In both of my own cases I have found it necessary to drain for a considerable period. The best method by far of accomplishing this object is by the Cathcart drainage.

The same free motion of the arm which I obtained in my first case is equally evident in the present case (Fig. 3). The left lung has expanded more than I had believed possible—to the third rib. There is a marked left dorsal lateral curve, so that the vertebral ends of the ribs reach the posterior axillary line. The whole left chest wall is unexpectedly firm and protects well the heart, the pulsation of which is very evident and is still displaced to the right.

---

#### THE INFLUENCE OF THE X-RAY METHOD OF DIAGNOSIS UPON THE TREAT- MENT OF FRACTURES.

---

BY CHARLES LESTER LEONARD, A.M., M.D.,  
Department of Clinical Surgery, University of Pennsylvania.

---

The discovery of a new and more accurate method of diagnosis, or of a shorter and more effective treatment, is always welcomed by the profession with an enthusiasm and eagerness which is often in excess of the true value of the method; and it is only after a long and severe trial that its merit can be determined.

Roentgen's discovery and its application to surgery was no exception, but during the two years that have elapsed since its introduction, the *x*-ray has demonstrated its scientific value even to the most skeptical. There have been many failures where it has been employed, and many foreign bodies "located" that could not be removed. These failures, however, were not the fault of the method *per se*, but of the crude and inaccurate manner in which it was employed. Accurate results can never be obtained by crude methods or instruments, and now that methods and instruments of precision have been intro-

duced in the application of the *x*-ray to surgery, these failures are rapidly decreasing in frequency, and as experience grows greater will become practically unknown.

It cannot be expected of any new method of diagnosis that it will replace or at first even equal methods which have attained accuracy and scientific precision by the study and experience of generations of observers, and yet this new method of diagnosis has already produced results which markedly affect the treatment of certain forms of fracture.

The amount of accuracy and the additional knowledge which can now be obtained by the aid of the *x*-ray picture is very great, and the practitioner who desires the best functional result for his patient will demand this additional aid in making his diagnosis complete and determining the best method of treatment; or at least will have skiagraphs taken to show the correctness of the treatment and to determine when changes should take place.

Fractures occurring in the shaft of long bones are not greatly benefited by this method unless it be in those difficult cases where the symptoms are rendered obscure by the thickness of the limb, the form of the fracture, or the contiguity of a neighboring sound bone. The greatest service which the *x*-ray renders is in the exact determination of the form of fracture in those difficult cases where a joint may be involved. The rapid swelling which always follows an injury near a joint renders the diagnosis difficult, while the exudate destroys any marked crepitus. Thus the determination of the exact line of fractures makes possible the adoption of a line of treatment, which would otherwise often be impossible. The point where danger is to be expected from exuberant callus, or the blocking of the joint by overlapping of the fragments, is made clear and readily avoided by appropriate treatment, which instead of being general and applying to all forms of injury about a joint, may be directed to the treatment of that particular case, with a much better functional result. In many instances fractures that lie wholly within the capsule of the joint and thus escape detection are distinctly shown and are rendered amenable to treatment other than that for "bad sprains."

Many fractures which have been described as rare have been shown by this method to have been rarely detected, while the exact determination of the form of the fracture and the recognition of minute comminuted frag-

ments have rendered coaptation more precise and the result of treatment more perfect.

In cases of delayed union or of ununited fracture, or where fibrous union is suspected, the x-ray picture shows the presence or absence of bone salts in the callus, the line of fracture in cases of fibrous union, or the maladjustment of the fragments, which has caused the poor result, while it aids the surgeon in determining the exact treatment necessary for the individual case.

The influence of this knowledge on treatment can scarcely be estimated, but the functional results obtained in many cases prove its great value. To secure the best results accurate methods must be employed and skiagraphs must be taken from more than one point, as inaccurate methods are liable to produce distorted images and a single picture may show the least deformity. One of the greatest influences of this method upon the treatment of fractures is the change it is bringing about in prognosis. Antisepsis has robbed the compound fracture of its gravity, and the skiagraph has shown that in many cases the simple fracture is much more dangerous and liable to be followed by greater deformity and loss of function, and that its name is often a misnomer. This result has produced a strong influence for a change in our nomenclature of fractures, the terms open and closed being substituted for simple and compound.

The most important change produced has been in the treatment of certain "simple" fractures, and the old but true saying applied by Sir Benjamin Ward Richardson to the treatment of obscure abdominal injuries should be applied to many of these simple fractures: "Because we are in the dark let us let in the light."

The x-ray has enlightened the darkness of fracture diagnosis and has shown that advancing surgery demands that we let the daylight into our treatment of many of these cases; they should be laid open and the bone exposed to the eye of the surgeon. Under perfect asepsis there is no danger commensurate with the advantages gained. Blood-clots can be removed, perfect approximation can be secured and maintained by appropriate wiring, pegging, or plates, and overlapping and distortion absolutely prevented.

Gross lesions and irregularities in outline can be detected with the fluoroscope; minute detail and accurate knowledge, essentials in the directing of treatment, can only be obtained in skiagraphs. The fluoroscope, how-

ever, may be used with effect in the adjustment of the fragments, the symmetry of the bones and the interosseous spaces being maintained with greater accuracy. After the fracture has been set and the dressings applied, a skiagraph taken through the dressings gives absolute proof that the proper adjustment has been made.

Among the fractures to which the author has applied this method of diagnosis with great benefit to the after-treatment are: Fractures of the phalanges; Colles' fractures; fracture of the styloid process of the ulna, its shaft, the coronoid process, the olecranon; fractures of the shaft of the radius, its surgical neck; intracapsular fractures of the articular surface of the humerus, various fractures of its condyles entering the joint; supra-condyloid fracture; fracture of the shaft, the surgical neck; fractures of the coracoid and coronoid processes of the scapula; simple, comminuted and green-stick fractures of the clavicle; fractures of the lower jaw; fracture of the axis; fractures of the femur in various parts of the shaft and condyles; fracture of the patella; fractures involving the articular surface of the tibia; spiral fractures of the tibia with fracture of the fibula; various forms of Potts' fracture, including chipping off of the posterior articular surface and linear fracture of the external maleolus; fractures of the astragalus, the os calcis, the metatarsal bones, and phalanges; and besides numerous instances of epiphyseal separation. In these latter cases the diagnosis is extremely valuable on account of the absence of ordinary symptoms, and the bearing upon treatment is always very great. In all cases where a former injury existed and a refracture has taken place, or a fracture of a neighboring bone, the service rendered is always very great, as the old distortion renders the accurate setting of the fragments almost impossible, as the normal can never be attained. Here, therefore, the treatment is markedly benefited by this method.

The majority of the cases studied were brought to the laboratory; many of them were private patients, while in a number of instances where the patient was unable to come to the laboratory the skiagraphs were made by his bedside. The benefits of this method of diagnosis upon the treatment of fractures is not restricted to hospital practise; developments and improvements in construction make the apparatus readily transportable and render its use in general practise possible.

There seems to be no doubt that the only

ground for damages in suits for malpractice must be, as formerly, based upon expert testimony as to the amount of deformity and functional disability of the patient. The skiagraph can only show that the fracture had been properly set by the surgeon, and that the resulting deformity was the fault of the patient. Skiagraphs of old fractures with perfect functional results do not show symmetry, and it should not be demanded, unless the patient allows the surgeon a better opportunity, as by open operation, for treating.

There is, however, reasonable ground for holding that unless a skiagraphic examination of the fracture has been made, or at least suggested by the practitioner and declined by the patient, it cannot hereafter be said that where functional disability exists the practitioner has employed all reasonable and ordinary means, to the best of his ability, in the treatment of the fracture.

*NOTE ON THE DRAINAGE OF LARGE CAVITIES AFTER SURGICAL OPERATIONS.*

HEATON in the *British Medical Journal* of January 22, 1898, says when a hollow organ such as the urinary or gall-bladder has been opened, or when a large suppurating cavity has to be drained, the surgeon after his operation often has much difficulty in keeping the patient and his dressings dry and clean. If it be some intraperitoneal structure, such as a suppurating gall-bladder, liver abscess, or suppurating pelvic cyst which has been opened and then stitched to the parietal peritoneum, some efficient method of drainage during the first few days becomes of vital importance. The leakage of pus or other irritating fluid in the first few hours after the operation, before the cavity of the peritoneum has been shut off by plastic inflammation, has frequently been the cause of a spreading fatal peritonitis. But even when a hollow organ has been opened without involving the peritoneum—as in the case of a suprapubic opening into the urinary bladder—if the discharge be at all profuse, there will be considerable difficulty in keeping the dressing dry. It is only by an almost constant changing of dressings and the use of large quantities of absorbent materials for collecting the escaping urine that the patient can be kept at all dry and clean; and despite every care in nursing, the bed is apt to get wet and the patient chilled.

During the past twelve months the writer has tried several modes of drainage with a view of obviating this, and has at length found one which he believes to be both simple, efficient, and inexpensive. He lays no claim to originality in the principle of the apparatus. The idea, indeed, was suggested by seeing the siphon arrangement used by dentists for the mouth during their operations.

The principle of the apparatus is the keeping up of a continuous slight siphon action from the cavity to be drained by means of a modified Sprengel's pump. Only sufficient suction is required to keep up a siphon action; indeed, any powerful suction is apt to be injurious to the tissues of the patient.

The apparatus consists of a reservoir capable of holding about two gallons, which is connected by means of the tube with the upper limb of a glass Sprengel pump, which is usually fixed to one of the legs of the patient's bedstead. The side tube of the pump is connected by means of a second piece of drainage tubing with a perforated glass bulb, which is placed in the cavity to be drained.

When water is allowed to trickle very slowly from the reservoir through the pump into a pan placed below to receive it, sufficient siphon action is maintained in the side tube to remove even the smallest quantity of fluid as it collects in the cavity to be drained, and this passes down with the water from the reservoir into the vessel beneath the bedstead, leaving the patient and his bed quite dry.

The chief difficulty experienced was in securing a satisfactory glass ending to be placed in the cavity. When an ordinary piece of glass tubing was used, or one perforated at the sides, the wall of the cavity to be drained was soon sucked into the open end and lateral openings, giving the patient pain and putting an end to all siphon action.

This difficulty is overcome by having two tubes, an outer one perforated at the sides, which encloses an inner one which is connected with the pump. Fluid as fast as it collects in the cavity trickles through the perforations of the outer tube, and is then sucked up by the open end of the inner tube. Several such glass endings have been tried, varying in size and shape with the wound and cavity to be dressed.

During the past six months the author has used this apparatus on six patients after operation.

### THE TREATMENT OF EXCESSIVE TYMPANITES.

There are three conditions in which excessive tympanites becomes a symptom of considerable importance, namely, typhoid fever, intestinal obstruction in its various forms, and in forms of pulmonary disease, chiefly pneumonia, in which the pressure of the gas upon the diaphragm and the thoracic viscera gives the patient much distress. Of course there are many other diseases in which a considerable quantity of gas may form at times in the stomach and intestines, yet it is in these three instances that we have named that it most frequently gives rise to serious discomfort or even danger. Under these circumstances the question at once arises as to what is the best method to give relief to the patient. In the majority of cases of typhoid fever this condition can be prevented, if the patient is seen early in his attack, by a proper direction of the diet and control of the bowels, using mild purgatives when they are needed to overcome constipation and mild antiperi-

statics when diarrhea becomes excessive. In a proportion of cases, however, even these precautions are not successful in warding off this complication, and under these circumstances it is our custom to direct that a turpentine stupe as hot as the patient can bear shall be placed over the abdomen and allowed to remain until it produces considerable counter-irritation. The period during which it remains in contact with the skin varies of course with the susceptibility of that patient's skin to this irritant. It may be that other counter-irritants are equally useful, but experience has seemed to indicate to us that turpentine is the most efficient.

If the tympanitic distention is not relieved by this application, a rectal injection of two to four ounces of milk of asafetida, pure or diluted half with water, is resorted to, and if this does not give relief a few drops of turpentine are added to a fresh injection of milk of asafetida, care being taken that the turpentine is thoroughly broken up in the asafetida emulsion so that no separate drops of the irritant oil will come in contact with the rectal mucous membrane. In other cases turpentine made into an emulsion with starch water, or thoroughly mixed with sweet oil, and given by rectal injection is equally efficient; but if all these remedies fail, then the rectal tube passed well up into the sigmoid flexure as far as possible and as gently as possible will generally allow the passage of the wind. Should these comparatively moderate means fail to give the patient relief, the question at once arises as to what other means there are at our disposal, and in this connection it is interesting to recall the very careful and able studies made by Ogle, of London, a number of years ago upon the subject of puncture of the abdomen for excessive tympanites. This investigator has collected from the experience of a large number of medical and surgical friends a great number of cases, which he has placed together in a complete essay. The result of his study is that in a certain proportion of cases puncture of the abdominal wall and intestine is safe and expedient and often followed by good results, and that in cases which are necessarily fatal its use will often render the patient's death much more easy than had the distention been allowed to remain or increase.

In Ogle's studies it was found that the operation is suited chiefly to those cases which have distention of the colon and stomach, for the numerous coils and kinks

of the small intestine and the fact that its caliber is much less than either of the viscera which we have named render accurate puncture difficult unless the knuckle of distended gut is particularly prominent. It seems evident, too, that puncture of the stomach is rarely if ever justifiable, because great distention of this viscus can nearly always be relieved by the use of the stomach tube or esophageal tube. It is only when grave obstruction to the esophagus or cardiac orifice exists that puncture for distention of this organ is permissible. Ogle believes that incurable cases of bowel obstruction are relieved of their most distressing symptoms by this means, and that curable cases are greatly aided by it since by this means vital organs are relieved from pressure and purgative drugs which before the gas was withdrawn could not move the bowels have an opportunity of unloading them.

It goes without saying that in making the puncture careful antiseptic precautions as to the condition of the nails and the patient's skin over the abdominal area are to be taken. The skin should be as carefully prepared as it would be for an abdominal incision, and the cannula or hypodermic needle which is used for puncturing purposes should be as small as possible in order that the wound in the abdominal parietes and particularly in the wall of the gut may be so minute that the muscular fibers will immediately close it when the needle is withdrawn. Further than this, if a large needle is used which has to be reinforced by a trocar passed through it, this trocar, the point of which should be sharp, should not have triangular edges but be perfectly round, in order that the puncture can remain open; and, again, as there is a certain amount of danger in withdrawing the needle of infecting the peritoneum or the abdominal wound by minute portions of the intestinal contents which may adhere to the needle, it may be advisable to allow a small quantity of saline fluid to flow inwards through the needle while it is still *in situ* after gas has ceased to come away from it, in order that any intestinal contents in its caliber may be washed back into the bowel and not withdrawn into the wound. When it is considered what grave insults the peritoneum will receive without resentment when it is in a healthy condition, the danger of infection in the way that we have hinted at cannot be very great. On the other hand, it is not to be forgotten that in case of intestinal obstruction in particular the susceptibility of the peritoneum

to infection is greatly increased. It is better to make a number of punctures in various portions of the bowel for the purpose of relieving the gas, using in each instance a fine cannula or needle, than it is to use one or two punctures with a large cannula. Ogle asserts that fecal extravasation has never in his experience followed such punctures, nor have they given rise to adhesions; and, further, that should more serious operative procedures be required these punctures in no way increase the danger to the patient. In an editorial which was published in the *Medical News* some years ago the writer mentioned a case in which the ingestion of a number of pigs' feet which lodged in the lower colon caused intestinal obstruction to such an extent that all purgatives and injections were futile, and yet the cardiac distress was so great as to force the writer to the use of hypodermic needles, which were inserted at various points along the course of the colon. Gas rushed through these for fifteen minutes before the colon became entirely collapsed, but after its collapse the purgatives, which had been administered, acted and the obstruction was removed. Recovery followed.

We have called attention to this means of treatment of severe tympanites not because we think it should be used in many cases, but because it seems a justifiable operation in some instances. It is not to be resorted to carelessly, nor until every other means of greater safety for the removal of the flatus has been carried out; but as a last resource which will sometimes succeed, sometimes fail, in relieving the distention, and which is not so dangerous as to seriously imperil the patient's recovery. We believe that the physician should always remember this method of giving relief.

---

#### THE QUESTION OF DIET IN TYPHOID FEVER.

---

One of the gravest dangers which threatens the continuous success of the busy practitioner is the tendency to relapse into what is known as routine treatment, which consists either in prescribing identical preparations to patients with the same general disease, but with different manifestations, or adhering rigidly to fixed lines of diet when a little thought and care would enable him to vary the diet, and so improve the nutrition of the patient. At least he need not enforce strict adherence to a particular line of food products.

In no disease is the importance of liberal feeding greater than in typhoid fever, for in this malady the patient, through a number of weeks, has his strength continually sapped by fever, diarrhea, and the various complications of this malady, with the result that at the end of even a mild attack he finds himself in convalescence miserably weak and lacking both nervous and muscular energy. It is a noteworthy fact, familiar even to the laity, that this lack of power of mind and body often lasts for many months after apparent recovery has taken place. The question naturally arises whether this atony and asthenia are an unavoidable consequence of the disease, and if so, whether it is possible to modify them to such an extent that convalescence may be more rapid and that recovery from the attack itself may be the sooner arrived at. It has been the custom of a great number of the profession for many years to order an absolute milk diet for patients suffering from typhoid fever, and to continue them on this diet for a number of days or even a week after the fever has disappeared and the temperature of the patient has been normal. Further than this, this diet is frequently insisted on when complications of typhoid fever arise which still further aid in decreasing the patient's vitality, and often a milk diet is insisted upon when it seriously disagrees with the patient, who because of idiosyncrasy, or because of some complication of his disease, is unable to digest milk properly. We have reached these conclusions not only from general and personal experience in which we have recently had ample opportunity to become convinced of this matter, but by reason of an article published by Dr. Frederick C. Shattuck, of Boston, upon this topic. After some general considerations he tells us that from 1886 to 1893, 233 cases of typhoid fever were treated in the Massachusetts General Hospital under a milk diet, with a mortality of ten per cent.; from 1892 to 1897, 147 cases have been treated under a much more extended diet, with a mortality of 8.1 per cent. He recognizes fully the liability to error in reckoning from too small figures in any infectious disease, and while he does not urge that this slight decrease in mortality may have been due to the more liberal diet allowed, it certainly points to the fact, as he thinks, that the more liberal allowance of food has no deleterious influence.

Dr. Shattuck believes that we should treat the patient rather than the disease, and

feeding him with reference to his digestive power rather than solely with reference to his fever, particularly as there are many other articles of diet than milk which can by no possibility exercise a harmful influence upon the intestinal ulceration. The diet list which he allows and which would certainly be considered very liberal in the average hospital and in many cases of private practice is as follows:

1. Milk, hot or cold, with or without salt, diluted with lime-water, soda-water, apollinaris, vichy; peptonized milk; cream and water (*i.e.*, less albumen); milk with white of egg, buttermilk, kumiss, matzoon, milk whey, milk with tea, coffee, cocoa.

2. Soups: beef, veal, chicken, tomato, potato, oyster, mutton, pea, bean, squash; carefully strained and thickened with rice (powdered), arrowroot, flour, milk or cream, egg, barley.

3. Horlick's food, Mellin's food, malted milk, somatose.

4. Beef juice.

5. Gruels: strained corn-meal, crackers, flour, barley-water, toast-water, albumen, water with lemon-juice.

6. Ice-cream.

7. Eggs, soft boiled or raw; egg-nog.

8. Finely minced lean meat, scraped beef; the soft part of raw oysters; soft crackers with milk or broth; soft puddings without raisins; soft toast without crust; blanc mange, wine jelly, apple sauce, and macaroni.

There are several articles in this list which we believe few, if any, typhoid fever patients ought to receive, and these are the soups, the beef juice, and the finely minced lean beef. In our experience all of these preparations tend to produce or to aggravate pre-existing diarrhea; and beef broth, as is well known, provides a very favorable culture medium for the typhoid bacillus. We have frequently seen the use of animal broths substituted for milk, and active, ill-smelling diarrhea with great flatulence has followed. To the list just given we may add soft custards, and instead of limiting the patient to milk with white of egg we have recently seen most valuable results follow the administration of egg boiled just long enough to take away its raw taste and yet not to harden the white. From one to six eggs prepared in this manner and administered to the patient by means of a spoon or in a cup, if he is strong enough to drink the egg, will do much towards maintaining strength, particularly in those cases where milk disagrees.

*THE IMPORTANCE OF MAINTAINING  
BODILY TEMPERATURE DURING  
OPERATIONS*

We have from time to time called attention in the *GAZETTE* to the great necessity of maintaining bodily temperature after severe injuries and during surgical operations: First, because the operation usually necessitates considerable exposure of the patient's body; second, because the anesthetic, which is used, of itself aids very greatly in the dissipation of heat; and third, because heat is an absolute necessity to the proper carrying out of vital functions. Curiously enough, this very valuable aid to the maintenance of vitality is largely ignored by surgeons and physicians, and the writer has frequently seen patients suffering from the results of severe hemorrhage no more warmly covered than the average ward patients, and very rarely he has seen such patients provided with a sufficient amount of external heat properly applied to be of material advantage. It is true that surgeons almost invariably surround patients after an operation with hot bottles or hot-water bags, but this is equivalent to locking the door after the horse is stolen. It is much better for the patient that measures be taken before and during the operation to maintain his temperature. By so doing we firmly believe that many cases of severe bronchitis, pneumonia and suppression of renal function by reason of congestion will be avoided. In other words, it is our opinion that a certain proportion of the respiratory and renal difficulties which arise after the use of an anesthetic depend more upon the exposure to which a patient has been subjected than to the effects of the drug which he has inhaled.

The well known experiments of Lauder Brunton, who proved that rabbits could take, with impunity, otherwise fatal doses of chloral if the animals were provided with external heat, indicate the necessity of this means of treatment in cases of poisoning by depressant drugs, and the fact that investigators of the motor area of the cerebrum invariably place the monkey, or other animal upon which they are experimenting, upon a hot-water bed is another indication that patients may be benefited by a similar line of treatment. Indeed, one world-famous investigator in this line informed the writer of this editorial that all his early experiments upon cerebral localization were handicapped or rendered useless by the grave depression into which the monkeys which he had experimented upon

speedily passed when etherized, or chloroformed, if not supplied with external heat. Further, that without this external heat they all invariably died after recovery from the anesthetic. As soon as the hot-water bed was provided for them almost all, if not all, invariably recovered. Although this is a matter which the writer of this editorial has emphatically insisted upon in his *Text-book of Therapeutics* and to his classes at the Jefferson Medical College for a number of years, attention has again been called to it by a paper published by Dr. John S. Miller, of St. Joseph's Hospital, Philadelphia, upon the "Application of Heat in Anticipation of Surgical Shock as a Prophylactic Measure."

In discussing the vital necessity of maintaining bodily temperature in traumatic and nervous shock, and the still more vital necessity of regenerating heat after it has been dissipated, Dr. Miller has published a figure showing an arrangement by which long hot-water bags, of similar size and shape to those used for sawdust in the fixation of a limb after fracture, may be placed between the limbs and alongside the patient in order to provide him with sufficient heat. He also concludes his paper by that frequently repeated yet constantly needed warning that the patient, while partially anesthetized by shock or by a drug, shall not be burnt by bringing in contact with his body a brick, iron or hot-water bag containing sufficient heat to produce a burn. Even under the care of the most skilful surgeons nurses will at times in the hurry of completing the patient's toilet and arranging the bed surround him with bottles which produce severe burns, and we have recently met with a case in which the patient was confined to her bed for one week because of the operation itself, and then for four weeks more in order that a severe burn of the thigh and calf produced in the manner spoken of might have an opportunity to heal. The application of heat is therefore much like the application of any other remedial measure; it must be employed at the right time, in the right place, and in the proper degree.

---

*THE TREATMENT OF GONORRHEA BY  
PROLONGED INJECTIONS OF  
PROTARGOL.*

When so many new drugs are exploited before the profession, often for distinctly commercial reasons and on insufficient clinical data, we have reason to be conservative

in accepting any one person's dictum in regard to the greater efficacy of a new preparation. When, however, a man as well known for his careful scientific work as is Neisser announces that he has had better, quicker and more permanent results from the use of protargol in gonorrhea than from any other single or combined remedies, this statement is worthy of serious attention and the drug should be given an extended trial.

Neisser prefaces his remarks on this comparatively new silver salt by some observations on irrigation treatment which he characterizes as difficult of execution, as no more efficacious than other methods in the large proportion of cases, and as likely to be attended by serious complications. With all these contentions those most experienced in irrigation will be inclined to disagree. Neisser himself acknowledges that in individual obstinate cases he employs this method. Hand injections, however, he characterizes as simple and readily applied by the patient. The syringe should contain at least  $2\frac{1}{2}$  to  $3\frac{1}{2}$  drachms, and the physician must see that the patient understands precisely how the injection is made. The ideal medicament is one which will not be irritating to the mucous membrane, but will none the less act as a germicide upon the gonococci. He has tried silver nitrate, argentum, ichthyol, and oxy-cyanate of mercury, but far superior to all these he finds protargol. This contains 8.3 per cent. of silver. It is a chemical combination of silver with proteid and forms a yellowish, fine powder which is readily dissolved by being shaken with water. This solution is not precipitated by dilute sodium chloride or hydrochloric acid, hence it is likely to penetrate deeply into the tissues.

In solutions of one-fourth to one per cent. argonin it is practically not irritating. A continuously acting application can be made, since there is no chemical combination by which the salt is decomposed. Long-continued application is particularly potent. This may be accomplished by single injections which are kept in the urethra for thirty minutes. The method of procedure is as follows:

First, search is made to determine whether gonococci are present, whether they are present in both the posterior and anterior urethra, and whether they are present in threads pressed out of the prostatic follicles. When these latter show gonococci, instillations are used. Injections are repeated thrice daily after urination. Twice the liquid is

kept in the urethra for five minutes, the third time for thirty minutes. The more abundant the secretion the more frequent the injections. Shortly, often in a very few days, these prolonged injections can be discontinued, and finally two of the injections can be made of the ordinary astringents, such as two and a half per cent. suspensions of bismuth or of thioform or of xeroform, employing as a suspension medium water or boric acid solution, or one-fourth-per-cent. zinc sulphate solution or twenty-per-cent. glycerin.

The great convenience of the treatment lies in the fact that the patient is not compelled to keep up the applications for a long period, though it is not the rapidity but the permanence of the cure which should be our aim. Even when gonococci disappear in twenty-four to forty-eight hours the patient should be instructed to continue the prolonged injections once daily for a week.

Microscopic control must be continued throughout, and only after repeatedly negative microscopic findings is the treatment to be abandoned. The physician should be slow in discontinuing his treatment.

In the beginning one-fourth-per-cent. solution should be employed. This should be increased in strength until one-per-cent. concentration is reached. In chronic cases the penetrating effect of protargol is well demonstrated, but it will be usually necessary before cure is accomplished to produce an acute inflammation, preferably by means of argentamin injections from 1:4000 to 1:2000.

As a result of his experience in hospital and private practise Neisser states that he has never had from any other drug such rapid, satisfactory and sure cures.

Goldenberg contributes an article which in the main confirms the favorable opinion of protargol expressed by Neisser. He states that the treatment is absolutely painless and there is no evidence of local irritation. In some cases after the disappearance of the gonococci a slight discharge persisted, which subsided after the conjoined use of astringent injections.

---

## Reports on Therapeutic Progress

---

### CALOMEL AND ACIDS.

Ever since calomel was introduced into therapeutics classic authors have drawn attention to the minute precautions that its use requires if one wishes to avoid serious results. It is well known that this substance

is unstable. Chemistry teaches that it is easily decomposed upon contact with salts and acids, and is transformed into corrosive sublimate. There are authors who will not admit the truth of this idea. They hold that the cases of poisoning observed are due to idiosyncrasies; others assure us that they have never found sublimate in the digestive tract; others again have the theory of intoxication, and think that the accidents arise from a reaction between calomel and albumen. The dangers that this drug present cannot be contested, as the experiments of Ottolenghi prove. This author has given calomel in therapeutical doses to dogs and compelled them to drink salts and acids. The animals always presented symptoms of intoxication, which appeared with more rapidity and severity than if the calomel had been taken alone. In these experiments the symptoms were not the same as those observed after the ingestion of corrosive sublimate. Ottolenghi affirms that, contrary to the current opinion, calomel is not decomposed in the stomach; in fact, if we place calomel in solutions of salts or acids, no phenomenon will appear if the temperature is no higher than that of the body, 37°C. That which does not take place in the laboratory does not take place in the stomach in those cases to which we refer. The exaggeration of the toxic effect of calomel after the ingestion of salts or acids arises from the fact that its combination with albuminoid substances contained in the stomach will be facilitated and will yield products much more soluble, so that calomel, which is normally absorbed in very small quantities, will pass in much larger amounts into the circulation, thus provoking signs of grave intoxication.—*Medical Record*, Oct. 30, 1897.

#### THE SYMPTOMATIC TREATMENT OF EXOPHTHALMIC GOITRE.

The *Journal des Praticiens* of October 16, 1897, contains an article upon this subject by DEGU. The most important symptomatic signs to be combated are the cardiac disturbances, which are usually manifested in symptoms of feebleness of this organ. In some of these cases digitalis is a valuable drug, in other cases it fails to do good. It is particularly indicated, according to Huchard, in those instances in which the heart is greatly disturbed in its rhythm and power. In these cases the digitalis exercises a valuable sedative effect and should be given in small doses.

The murmurs which are heard in the heart in many cases of exophthalmic goitre are not to be regarded as valvular affections, but as temporary symptoms of the disease. For the palpitations, which are annoying symptoms, Ging has recommended the application of cold compresses to the præcordium, or in their place atomization by ether or chloride of ethyl or the use of an ice-bag. All of these applications are practically without danger. Care, however, must be taken that they are not so continued as to destroy the integrity of the skin. In some cases strophanthus is better than digitalis. In those instances where there is considerable cardiac pain or pseudo-angina, nitroglycerin is useful. Counter-irritation produced by chloroform compresses is of value. Aconite is also useful in some instances. If albuminuria is present a milk diet should be insisted upon.

Dieulafoy has strongly recommended the following prescription in cases of great eryth-  
rism of the cardio-vascular apparatus:

- ℞ Powdered ipecac, ¼ grain;  
Extract of opium, 1-10 grain;  
Powdered digitalis, ¼ grain.

Make into one pill and give four to six in twenty-four hours.

On the other hand, tincture of veratrum viride, ten drops a day increased to twenty drops progressively, has been recommended by Sée as a valuable remedy, and small quantities of veratrine ointment may be applied over the præcordium with advantage. Another line of treatment is that of Handfield Jones, which, however, is rejected by the author of this paper, namely, the administration of strychnine. Ergot has given good results in some of Huchard's cases, particularly when combined with the hydrobromate of quinine as follows:

- ℞ Hydrobromate of quinine,  
Ergot, of each ¼ drachm.

Make into four pills; give three to six a day.

The best hypnotics for the insomnia are chloral and trional. Arsenic may be given for the general improvement of the patient's nutrition.

#### THE USE OF VINEGAR FOR THE VOMITING PRODUCED BY CHLOROFORM.

*La Médecine Moderne* quotes the observation of LEWIN that out of 174 cases of vomiting following the administration of chloroform he was able to relieve 125 patients by causing them to inhale the fumes of vinegar, the vinegar having previously been placed upon a towel. The method consists in placing a

small piece of linen which has been wet with vinegar over the face of the patient for a number of hours, after the chloroform mask has been removed. If the vomiting returns after this treatment is stopped a renewal of it will be sufficient to check the relapse.

Lewin believes that in the elimination of chloroform from the lung it is decomposed into hydrochloric acid and chlorine and that these irritating substances are responsible for the attack of vomiting, and that the inhalation of the vapor of the vinegar produces trichloroacetic acid, which does not produce vomiting.

#### LACTIC ACID IN A CASE OF ARTHRITIS DEFORMANS.

ZOLOTAVINE (*La Médecine Moderne*, Sept. 18, 1897) used lactic acid with success in an old case of arthritis deformans, administering daily ten drops of this drug upon an empty stomach, and allowing no food for an hour and a half afterward. The disease had lasted for ten years, and for a year the patient had not been able to leave her bed. The dose of the medicine was gradually increased to forty drops daily. At the end of three weeks the action of the acid was manifest; the articular pains were so relieved that the woman was able to get out of bed and walk a little; the circumference of the joints diminished slightly; nutrition improved and abdominal pains disappeared. No other medicine was used, and the only external treatment was a light massage. Improvement continued until the patient, at the time of writing, could walk without a cane and attend to her ordinary occupations.—*Medical News*, Oct. 30, 1897.

#### THE TREATMENT OF UREMIA.

In the *Journal des Praticiens* LE GENDRE recommends the following treatment: In eclamptic accidents we should use inhalations of chloroform and administer chloral and the bromides by injection. The suggestion that antipyrin be employed is not to be carried out, as this substance seems to decrease the urinary secretion. Some practitioners have resorted to compression of the carotid and others have employed hot baths. For the coma of uremia subcutaneous injections of caffeine and ether with inhalations of oxygen are to be employed. The dyspnea is to be combated in different ways, according to its cause. Should it be due to acute edema of the lung multiple scarifications and cuttings of the thorax may be resorted to,

oxygen given by inhalation, and the nitrite of amyl or nitroglycerin is to be administered. Sometimes this form of dyspnea is relieved by the injection of morphine. In the chronic dyspnea of uremia with nightly paroxysms bleeding is not indicated, but morphine is often a useful drug. Should the dyspnea depend upon nervousness of the heart cardiac tonics such as digitalis are valuable. On the other hand, should the dyspnea be mechanical in the sense that it results from hydropericardium or hydrothorax, these cavities must be tapped and the fluid withdrawn, or the condition combated by the use of diuretics.

In regard to the incoercible vomiting small pieces of ice, sips of seltzer water or frozen champagne, one or two drops of creosote or of the tincture of iodine in a spoonful of water may be useful, and oxygen water, chloroform water, or small doses of lactic acid or copious draughts of hot drinks may be used. In other instances lavage of the stomach is of value, particularly if the vomited material is ammoniacal, showing the elimination of urea into this viscus. In this condition Frerichs has recommended the use of chlorine water or benzoic acid. Should violent diarrhea exert itself it is to be controlled by large doses of bismuth, chalk, lactic acid, and nitrate of silver in pills.

#### THE TREATMENT OF APHTHOUS STOMATITIS.

The local treatment consists in the application to the mouth five or six times a day of any one of the following solutions:

- ℞ Borax, 1 drachm;  
Tincture of myrrh, 2 drachms;  
Syrup of mulberry, 2 ounces.
- ℞ Borax, 1 drachm;  
Tincture of benzoin,  $\frac{1}{4}$  drachm;  
Distilled water, 3 drachms;  
Simple syrup, 6 drachms.
- ℞ Phosphate of sodium,  $2\frac{1}{2}$  drachms;  
Orange-flower water, 1 ounce;  
Honey,  $1\frac{1}{4}$  ounces.
- ℞ Salicylic acid, 30 grains;  
Alcohol, 3 drachms;  
Glycerin, 6 drachms.

If the case is a grave one it may be wise in addition to order the following prescription for internal use:

- ℞ Chlorate of potassium, 15 grains;  
Distilled water, 3 ounces;  
Syrup of raspberry,  $2\frac{1}{2}$  drachms.
- A teaspoonful every two hours.

—*Journal des Praticiens.*

*ACCIDENTS DUE TO THE EMPLOYMENT OF ANTIPYRIN.*

The *Gazette Hebdomadaire de Médecine et de Chirurgie* of September 26, 1897, contains an article on this subject in which the writer refers to a thesis by M. V. Clement which, he says, is particularly instructive. The author devotes considerable space to the nature of the accidents which follow the immoderate use of antipyrin, giving a detailed account of those pertaining to the skin, the viscera, the nervous system, and the circulation, from which the following practical conclusions are reached:

1. Antipyrin should never be prescribed for very old people, for subjects attacked with non-compensated cardiac lesions, or for those in an adynamic condition.

2. In influenza and erysipelas it should always be associated with quinine and, in convalescence, with strychnine or caffeine.

3. In arthritic subjects, who are nearly always dyspeptics, it should be associated with an alkali (sodium bicarbonate or sodium benzoate) and prescribed in solution. If it cannot be taken except in a capsule, the patient should drink a quarter or half a glass of Vichy immediately after taking the capsule.

4. In tuberculous subjects twelve grains at a time should not be exceeded, and the condition of defervescence should be carefully watched. It is well in these cases to combine alcohol and antipyrin and give the latter in solution.

5. In diabetic subjects the association with alkalies is obligatory.

6. In children antipyrin may be administered without inconvenience even in amounts proportionately larger than in adults, provided it is given in divided doses. This tolerance depends as much upon the integrity of the renal functions as upon the mode of administration, which should nearly always be by the solution.

The writer calls attention to the fact that antipyrin given in powder, sometimes even in solution, has a special effect upon the mucous membrane of the stomach, and that this may be avoided by employing hypodermic injections. An injection done aseptically never gives place even to the least cutaneous disturbance.

The treatment of these accidents consists, naturally, in suspending the use of the drug. For the cutaneous accidents simple measures are generally sufficient. If it is a serious case of poisoning, injections of ether and

especially of caffeine should be resorted to. During convalescence alcohol, digitalis, strychnine, and small doses of quinine render great service.—*New York Medical Journal*, Oct. 30, 1897.

*THE THERAPEUTIC EFFECT OF ARTIFICIAL HYPEREMIA.*

BIER (*Münchener Medicinische Wochenschrift*, 1897, No. 32), who for some years has advocated artificial hyperemia as a successful method of treating tuberculous joints, has tried its effect in other diseases. Syphilitic foci of disease invariably were affected for the worse, and the growth of two sarcomata was rapidly increased. In gonorrheal articular rheumatism artificial hyperemia was almost always of marked benefit, but in acute articular rheumatism the results were variable. In chronic rheumatism and arthritis deformans the results were unequal, but generally very good.—*British Medical Journal*, Oct. 23, 1897.

*THE USE OF CALOMEL INJECTIONS IN LUPUS.*

In *La Presse Médicale Belge*, HASSELBERG records his experience in the treatment of lupus with calomel injections in four cases, and he believes that this method of treatment is destined to produce great results in the treatment of this troublesome cutaneous affection. The number of injections usually vary from three to twenty-five or thirty, but unfortunately no statement is made in the article as to the quantity of calomel injected at each dose; neither is there any definite statement as to the part of the body in which the injection was made.

The method of treatment is recommended in those cases which will not submit to or are not suitable for surgical interference.

*THE TREATMENT OF HEMOPHILIA WITH CHLORIDE OF CALCIUM.*

Physiologists have known for some time that lime salts play an essential part in the coagulation of the blood. This suggested to Dr. A. E. Wright the possibility of artificially increasing the power of coagulation. He made some valuable researches and showed that the administration of chloride of calcium caused a considerable increase. He found that in hemophilia the coagulation time could be reduced about one-half. He therefore suggested the use of this salt in the treat-

ment of hemophilia and other diseases attended with recurrent hemorrhages. His conclusions have been fully confirmed by the results, especially in the case of hemophilia, where they are even brilliant. But the value of the treatment appears still to be but little recognized. The following case, published by Dr. Clifford Perry, and abstracted in a recent number of the *Revue des Sciences Médicales*, is very definite evidence: Severe hemorrhage followed incision of a dental abscess in a case of hemophilia. Only after four hours' energetic work, and packing the whole space between the alveolar process and the cheek with gauze saturated with strong solution of perchloride of iron, did the hemorrhage cease. Later epistaxis and recurrence of hemorrhage from the wound took place, which ceased when the patient was on the verge of collapse. After six hours alarming hemorrhage again occurred, which all ordinary means failed to stop. Chloride of calcium was given in doses of two grains every four hours. In a few hours the effect was marked; a firm clot formed and the hemorrhage ceased.

#### THE TREATMENT OF LEG ULCERS.

The following treatment is suggested by the *Journal des Praticiens* of July 3, 1897: After rendering the surface of the ulcer antiseptic it is cauterized with nitrate of silver, followed by the application of boric acid. If this does not produce improvement the following ointment is applied daily:

- ℞ Carbolic acid, 30 minims;
- Boric acid, 2½ drachms;
- Powdered camphor, 2 drachms;
- Ichthyol, 5 drachms;
- Oil of sweet almonds, 2 drachms;
- Zinc ointment, 3 ounces.

#### THE EFFECTS OF RESISTANCE EXERCISE UPON THE CIRCULATION IN MAN, LOCAL AND GENERAL.

In the *British Medical Journal* of October 16, 1897, BRUNTON and TUNNICLIFFE record a study of the effects of resistance exercise. The conclusions which they are able to formulate from their experiments fall under two heads: (1) Physiological; (2) Medical.

1. Physiological: (a) Locally, gentle exercise is followed by a dilatation of the muscular arterioles with an increased flow of blood through them. This is shown by the fact that after the contraction is over the pulsations in the muscle have a greater amplitude—that is, there is a greater distance

between the crest and hollow of each pulse wave than before the contraction. As these alterations in the circulation are purely local, the heart remaining the same, they can only be due to a local dilatation of the arterioles in the muscle, allowing them to empty themselves more rapidly during the cardiac diastole. (b) Generally, the effect of exercise so gentle as to cause no hurry in the respiration and no increased frequency in the pulse on the general blood-pressure is that during the exercise itself the pressure first rises above the normal, but begins to fall, even during the continuance of the exercise; continues to fall, so that at the end of the exercise it has usually reached the normal. After cessation of the exercise the pressure continues to fall. The pressure after the exercise may remain subnormal for half an hour or longer; after the expiration of this time it gradually rises again to its initial height.

These results may at first sight appear to differ from those of Oertel, who found that a rise in general blood-pressure invariably followed muscular exercise. The authors believe that the difference between his results and theirs depends upon the amount of exercise taken being different in the two cases. In his experiments the amount of exercise was sufficiently great to cause considerable strain. In one case, for example, the exercise consisted in making an ascent in forty minutes for which an hour was usually reckoned. Although he notes that no difficulty in breathing occurred, yet the respiration must certainly have been quickened.

If we compare the results of the author's experiments just mentioned with those which Brunton and Tunnicliffe found to follow massage, we notice that the primary rise of blood-pressure upon exertion is greater than that caused by massage, but that the subsequent fall is both greater and of longer duration.

2. General medical conclusions: (a) In cases where the heart is very feeble, so that the primary rise of blood-pressure caused by even gentle exercise may interfere with its action, massage is the mode of treatment best adapted for restoring the circulation. (b) That when the heart is sufficiently strong to bear the increased resistance presented to it by the primary rise of pressure occurring during exercise, gentle exercise is preferable to massage, inasmuch as the subsequent diminution of resistance is greater in amount and of longer duration. (c) The difference between their results and those of Oertel

affords a scientific basis for the practical rule which has been found so advantageous at Nauheim, namely, that the exercises shall not be carried to such an extent as to cause any acceleration of breathing on the part of the patient.

#### THE PREVENTION OF IODOFORM INTOXICATION.

SASSE is quoted by *Journal des Praticiens* of October 16, 1897, as recommending the following means of demonstrating in time a threatened iodoform intoxication, a condition which is not rare in surgical and gynecological practise. A test is made of the urine to note the quantity of iodine which is eliminated by it. A small pinch of powdered calomel is placed upon a saucer, and then a few drops of the urine to be examined is dropped upon it; a mixture of the urine and calomel is then made with a glass rod. If the urine contains a notable amount of iodine there is produced a well marked yellow discoloration, which should indicate that the iodoform is being absorbed in sufficient quantity to produce danger.

#### ADMINISTRATION OF ANESTHETICS THROUGH A TRACHEAL WOUND.

In the London *Lancet* of November 6, 1897, THOMAS ANNANDALE recalls the fact that in March, 1897, he published in the *Edinburgh Medical Journal* a short paper upon "Preliminary Tracheotomy as an Aid to Certain Operations." In this communication the writer has described and figured a simple appliance for keeping a patient under the influence of chloroform or ether in connection with operations which necessitated a previous tracheotomy. Since then he has used this appliance from time to time with success, but having found that the india-rubber tube connected to the tracheotomy tube was sometimes apt to get twisted at its point of connection and so interfere with respiration, and also that matters coughed up were not readily expelled through the long tube, he has had his apparatus improved so as to lessen these risks. This modified appliance was recently employed with perfect success in a case of excision of the entire larynx and portion of the trachea, together with a large and vascular thyroid tumor, the patient being now quite convalescent.

This improved apparatus is as follows: (1) An ordinary full-sized silver tracheotomy tube having its upper end extended for about

half an inch beyond the shield. (2) A silver cap, having a short tube of the same metal projecting at right angles from it and to which one end of an india-rubber tube is connected. The cap fits easily on the tracheotomy tube and is also turned around so as to allow the attached india-rubber tube to project on either side, whichever may be found most convenient for the administration of the anesthetic. (3) A portion of the india-rubber tubing; the length of this should be about two feet, but it may be used shorter or even a little longer. The diameter the author prefers is about half an inch. (4) An ordinary glass tumbler or other similar receptacle with a small piece of lint or absorbent wool placed at the bottom, upon which the chloroform or ether is from time to time sprinkled.

The writer prefers chloroform, but whatever anesthetic is used may in the first instance be held over the tracheotomy tube with the cap off, and when the time for the operation has come the cap with attached india-rubber tube is put on and the anesthetic inhaled from the tumbler, the anesthetist standing or, if he prefers, sitting well away from the operating table, holding the tumbler in one hand. For preventing saliva, blood or vomited matters passing into the air-passages during the operation the introduction of a piece of sponge or other plug into the trachea above the tracheotomy wound is usually satisfactory, but in the case of the excision of the entire larynx already referred to he has adopted a thoroughly effective and as far as he knows original method, and he is inclined to think that this plan may be used in other cases. The procedure was to pass round the trachea immediately above the tracheotomy wound an india-rubber cord and by means of it to ligature the canal temporarily so as completely to prevent the entrance of any fluids or other matters into the air-passages. When the ligature was removed at the completion of the operation above referred to, the walls of the trachea did not appear to have been injured by it. It is true that the condition of the tracheal rings in some instances might prevent such a ligature being perfectly effectual, but the writer is of opinion that this means of temporarily closing the trachea is worthy of consideration and trial.

The advantages, then, claimed for the appliance which the author speaks of are:

- (1) It is simple and at the same time effectual.
- (2) The cap being movable can if necessary

be at once disconnected from the tracheotomy tube, so as to allow mucus or other matters to be more easily expelled from the air-passages; this mobility also allows the cap and connected india-rubber tube to be turned round to either side. (3) It allows the anesthetic to be administered at some distance from the patient, and so does not interfere with the operative procedure. (4) The anesthetic when inhaled through the long tube is not likely to be so irritating to the air-passages as when it is more directly inhaled through the tracheotomy tube itself.

#### THE PREPARATION OF DIPHTHERIA ANTITOXIN.

A. T. BAZIN, in an article on the preparation of diphtheria antitoxin in the *British Medical Journal* of December 11, 1897, speaks of its use in treatment and thinks that he ought, while considering the effect of antitoxin on the local lesion, to refer to the employment of local treatment. The writer thinks it wise to condemn the practise of entirely withholding local treatment and trusting all to the antitoxin. It is simply a plan of counteracting the ravages of the Klebs-Loeffler bacillus, and trusting to a kind providence that streptococci and other pus organisms will not be absorbed from a highly absorptive surface in a state of impaired vitality. The course is not rational; as well treat a case of tertiary syphilitic ulceration with potassium iodide and neglect to cleanse the ulcers and treat the surrounding cellulitis. On the other hand, too rigorous local treatment is to be deplored. It smacks of the days of pepper, sulphur, lactic acid, and strong hydrogen peroxide. A median course which supplies a gently cleansing solution to the inflamed part is one to be recommended.

The depression so marked in diphtheria is replaced in one or two days by a feeling of well-being which is surprising. This is a most certain index of the effectiveness of the dose. Antitoxin also prevents the anemia so constantly caused by diphtheria, both by antagonizing this effect of the toxin and by shortening the disease. Convalescence is, therefore, very rapid.

The effect on the temperature is twofold: first, there is a reactionary rise of  $0.5^{\circ}$  to  $3^{\circ}$  F., followed in from four to six hours by a drop to or almost to normal, and, if the dose has been sufficiently large, a normal course thereafter. This condition is not constant,

but is the common one. If the dose has not been sufficient, the temperature will evince a tendency to rise to or above the level existing previous to the administration of the antitoxin.

The effect on the pulse is irregular. To a large extent the pulse, in rate and volume, responds to variations in the temperature. After twelve hours have elapsed from the time of injection a sudden change in cardiac action could hardly be attributed to the antitoxin.

The dosage followed by the author is that advocated by the American Pediatric Society: In cases of ordinary severity, children under one year 500 units; older children and adults, 1000 to 2000 units. In cases of increased severity, including laryngeal cases—and the author wishes to emphasize, nasal diphtheria—children under one year 1000 to 1500 units; older children and adults, 2000 to 3000 units.

If the lapse of eight to twelve hours have not brought about an amelioration of the symptoms, these doses should be repeated, and, if necessary, a third dose should be administered after a similar interval. It is better to be sure than sorry and therefore to err on the right side. With the use of concentrated serum where the effect is so rapidly seen and judged of, the same results may be obtained with somewhat smaller doses. But the physician must constantly be on the watch for apparently mild cases which are deceptive, and in these cases to administer the antitoxin with lavish hand. The importance of the early administration of the remedy cannot be too greatly emphasized; as the serum is innocuous it is not necessary—more, it is foolhardy—to wait for a bacteriological confirmation of the diagnosis. Clinical diagnosis, even “clinical suspicion,” to coin a term, is sufficient to warrant the injection of the serum, and then let the bacteriological examination be made rather to confirm the degree as to the necessity of continued isolation of the patient, and the immunization of those exposed.

There is a further use of antitoxic serum which the author alludes to, and one which is too often neglected at the present time—that of immunization of persons exposed to the contagion of diphtheria. The happy results obtained in hospitals and institutions for the care of children sufficiently recommend the procedure. To Dr. Hermann Biggs is especially due the credit of pursuing and investigating this branch of the antitoxin treatment, and in his article which appeared

in the *Medical News* of November 30, 1893, he points out that 50 to 300 units, dependent upon the size of the patient, should be given, and that the immunity thus conferred continues to be effective for a minimum period of thirty days.

Even to children suffering from other maladies, both acute and chronic, the immunizing dose is harmless, as in December, 1896, Bazin immunized nineteen children in a ward of the Montreal General Hospital and not a single disturbance of temperature or general condition could be detected. The contagion was conveyed to the ward by a case of conjunctival diphtheria and one other child became infected. On the following day all the inmates of the ward received an injection of antitoxin and no further cases developed.

#### THE ACTION OF THE ALKALOIDS OF OPIUM UPON PERISTALTIC MOTION.

After a careful review and discussion of the results obtained by other investigators V. VAMOSSY (*Rev. de Thérap.*, Aug. 15, 1897) describes in detail the method which he employed in arriving at the following conclusions in regard to the question: What is the cause which gives to opium a greater inhibitory action on the peristaltic motion of the intestines than morphine?

1. Morphine injected in the venous circulation has the power by its centric action to hinder the action transmitted by the pneumogastric to the centers, that its centripetal action is not transmitted by the centrifugal route to the intestine and does not provoke contractions.

2. Local injections of morphine into the intestines showed that the excitability and conductivity of the nervous system of the intestine undergoes a considerable diminution as the result of the local irritation.

3. The excitations which pass by the centrifugal motor channels to reach the intestinal wall encounter the terminal nerve fibers and ganglions in a state of narcosis.

4. Narcotine acts but slightly as an inhibitor of reflex excitability in the intestinal wall, and possesses no inhibitory action upon peristalsis.

5. Papaverine resembles morphine more closely in its action upon peristalsis, but its action is too unstable.

6. Thebaine augments intestinal excitability and provokes in consequence an intense peristalsis.

7. It can be no longer held that narceine acts in opium as an augmenter of inhibition to peristalsis in a manner similar to morphine.

8. Codeine exaggerates the intestinal excitability.

9. Cryptopinine and laudanine also act as augmenters of intestinal excitability.

As the result of his study the author concludes that opium does not owe its favorable influence upon the intestine to the presence of the accessory alkaloids which it contains.

#### MANGANESE BINOXIDE.

In the *Georgia Journal of Medicine and Surgery* for January, 1898, A. H. SMITH tells us that, in his opinion, among medicines having a specific action there is none which has given him more satisfaction than the bin-oxide of manganese. For many years he has prescribed it constantly for functional derangements of the uterus, and with a smaller percentage of failures than from any other drug with which he is acquainted. It has been equally serviceable when the menses were too profuse and when they were too scanty; when the interval between the periods was too short, and when it was too long. In this respect there is no other term that describes its action as the word "corrective." In the absence of organic disease it seems to have the power, in a great many cases, of bringing the menstrual function back to the normal standard in whatever direction the deviation from that standard may have been. Again and again the writer has seen an habitual interval of three weeks lengthened to the normal twenty-eight days, or a usual duration of eight days, for example, reduced to four or five. On the other hand, irregular or abnormally long intervals have been brought to regular four-weekly periods, and a scanty flow to a satisfactory quantity.

In painful menstruation not dependent upon anatomical conditions the writer has come to rely with great confidence upon the relief to be obtained from the bin-oxide. Beginning about four days before the expected period, and continuing until the flow is fully established, it will generally give a measure of relief for that time. It may, however, seem to be of little or no benefit on the first occasion, but if repeated for the next month an amelioration may be quite confidently predicted, and by perseverance during three or four periods complete and permanent relief is usually obtained.

The headache of a burning character, and limited to the vertex, which so frequently has a uterine origin, is often promptly relieved by two or three doses of the drug, administered at intervals of two or three hours, and this even when it occurs during the intervals of menstruation.

Finally, in the only instance in which he has employed the binocide for this purpose it gives decided relief to the hot flashes attending the menopause. If the patient takes a pill of two grains at bedtime, she passes a fairly comfortable night, whereas if the pill is omitted she wakes half a dozen times to find herself dripping with perspiration. The author has heretofore depended upon one of the nitrites in such cases, but there are persons who cannot bear them even in the smallest doses, and in such cases he intends to make trial of the manganese.

The author's experience with the drug convinces him that it controls in a marked degree the nervous disturbance emanating from the uterus. The effect is often too prompt to be attributable to a merely tonic action upon the general system, and he is forced to believe that it has a peculiar specific relation to the parts involved.

The dose is two grains three times a day, but as it is absolutely without unpleasant effects, it may be given in much larger quantity and at much shorter intervals. For its effect upon the periods it should be given for three or four days before the expected time and continued nearly or quite through the period, this being repeated for several consecutive months.

#### INTRAVENOUS INJECTIONS OF ARSENIC IN THE TREATMENT OF PSORIASIS.

HERXHEIMER (*La Semaine Médicale*, clxii, 1897) has employed these injections in twenty-eight cases, in twenty-five of which no other treatment was adopted. Of these twenty-five, ten were completely cured, six left the hospital much relieved, and nine were reported as still under treatment, all greatly improved, and three nearly cured. The commencing dose is one milligramme of arsenous acid, and this is increased daily by one milligramme up to fifteen milligrammes, the maximum dose, which is repeated daily till the eruption disappears, generally at the end of six or seven weeks. At the end of the first or beginning of the second week the patches become darker in color, and there is a more abundant production of scales; the eruption

then fades and disappears, the pigmentation occasionally persisting. The injections are generally well supported. Arsenical zona and diarrhea were met with in a fortnight in two cases, and a venous thrombosis, cured in a fortnight by rest of the affected limb, occurred in a third; slight thrombosis also occurred in another case.

The following is the method of procedure: After disinfection of the skin by soap, turpentine, ether, and sublimate, and the application of an Esmarch bandage above the elbow to render the veins prominent, the needle of a Pravaz syringe is introduced as nearly parallel to the skin as possible, and its penetration of the vein ascertained by withdrawing the piston. After the injection of one cubic centimeter of a limpid solution of arsenic of the desired strength, the wound is closed with oxide of zinc plaster. — *British Medical Journal*, Oct. 23, 1897.

#### THE DANGERS OF ARTIFICIAL RESPIRATION.

A. BROSCHE (*Deutsche Archiv für Klinische Medizin*, vol. lviii, p. 605) narrates that a man, aged twenty-two, fourteen days after his discharge from the hospital as convalescent from diphtheria, was seen to get up suddenly from the dinner table, take a few steps towards the door, and fall down. The doctor was called and found the man apparently dead; he nevertheless tried artificial respiration for a long time, but in vain. At the necropsy food was found in the trachea and bronchi, and the uvula and soft palate were edematous.

Was the entry of food into the air-passages during life the cause of death, or was death due to syncope? And did artificial respiration after death cause the entry of some of the gastric contents into the air-passages? To throw light on this question Brosch made a number of experiments on dead bodies. He opened the stomach, put fluid into it, closed up the opening again, and ligatured the pylorus; artificial respiration—Sylvester's method—was found to cause the aspiration of some of the gastric contents into the air-passages. In a control experiment he did not open the stomach, but contented himself with trying the effect of artificial respiration on the natural stomach contents. A similar result was quickly obtained, and the fluid contents of the stomach immediately began to fill the pharynx, flow out of the mouth, and enter the air-passages; the fluid

food was found in the trachea, main bronchi, and all the branches of the main bronchi.

Brosch discusses various methods—preliminary tracheotomy, artificial respiration after the manner of Schüller, Howard, and Marshall Hall—and comes to the conclusion that when there is reason to fear aspiration of gastric contents, the best way to avoid the possible fatal effects of artificial respiration is, before commencing the movements, to introduce an elastic tube into the esophagus. This he thinks will likewise help to prevent the falling back of the tongue. The tube should, however, be sufficiently stiff to avoid its being quite easily pressed flat, in which case its lumen would be obliterated and it would be rendered useless. It should also reach at least fifteen centimeters beyond the pharynx into the esophagus, and ten centimeters of the tube should project from the mouth and the outside end should be weighted down, so that, if any fluid comes out, it will not flow back into the pharynx again.—*British Medical Journal*, Oct. 23, 1897.

#### THE TREATMENT OF THE PUERPERIUM

In the *British Medical Journal* of October 23, 1897, Dr. A. H. WRIGHT gives us a view of the methods and results reached in the lying-in wards of the Toronto General Hospital. He tells us that before vaginal examinations the hands are washed for four minutes in hot water, using soap and a nail-brush; the nails are cleaned with a penknife; and then the hands are washed for two minutes in hot bichloride solution (1 to 2000), using a nail-brush again. The hands are then immersed in hot bichloride solution 1 to 1000 immediately before making an examination; and carbolyzed vaselin is used for a lubricant when required (generally not used). They use an ordinary minute-glass, such as is found in a kitchen for cooking eggs, to govern the time the hands are cleaned. The glass is attached to the wall near the delivery bed. It is reversible and takes six minutes to empty from one side to the other. There are on the glass notches to indicate three and four minutes. At the same time the accoucheur takes off his ordinary coat and puts on a clean white apron. The best apron is one that goes around the body, with sleeves which go to the elbows. [Both hands and forearms are bare.

The instruments, forceps, etc., are kept in a boiling solution of carbonate of sodium one-per-cent. for ten minutes before and

after they are used. Glass or rubber catheters are employed, and half a pint of a solution of carbonate of soda is passed through the catheter after it is used, and it is then placed in a bichloride solution, 1:1000.

After labor the vulva is washed with a warm soda solution, then with a bichloride solution, then a powder composed of boric acid and acetanilid is freely applied, and then the vulva is covered with a thin layer of absorbent cotton which has been taken from a bichloride solution. Over this is placed a sterilized absorbent pad.

The patient is prepared for the delivery table by the matron or nurse in accordance with fixed rules, which however are not printed. During labor the vulva is covered with a bichloride pad.

The printed rules and the homely cooking minute-glass were not popular at first. The resident assistants sometimes ignored them or obeyed the directions in a half-hearted way. The two years from 1891 to 1893 were a transitional period during which the rules did little or no good. The results were certainly discouraging, as a death from septicemia occurred in each of these years. Since November, 1893, their results have been better, as they had 500 deliveries without a death from any cause. Excepting in two cases, to which the writer refers again, the patients have gone out well, so far as they can be at that time. In no single instance since November, 1893, has a patient, transferred to another part of the hospital, died from pneumonia or any such disease. It happens that most of those women who died during the nine years were transferred to the General Hospital during illness, but these deaths are included in this record.

Before giving any further particulars as to mortality or morbidity the writer refers to certain details relating to matters which have given much anxious thought. In his private practise he has not used the vaginal douche either before during or after labor as routine practise for fifteen years. When he first commenced work at the hospital eleven years ago, he found certain members of the staff using the vaginal or uterine douche to a considerable extent. This has gradually become less common, until it has almost gone out of fashion. For some time a vaginal douche was given immediately before and after labor, and an intra-uterine douche was given when the temperature went up. During the last two years no douche has been given either before or after labor unless there

seemed to be some special indication for it. When there is evidence of a foul condition of the interior of the uterus causing sapremia, or something worse, the intra-uterine douche is sometimes used. The "rinsing" curette with the douche is employed occasionally. His own preference is to have the patient anesthetized, introduce his hand into the vagina, clean out the interior of the uterus with his finger-tips, and then wash out with a one-per-cent. solution of creolin.

The use of the forceps is discouraged. No resident assistant is allowed to apply the forceps without permission of the medical superintendent or a member of the visiting staff. They have a forceps delivery about once in twenty cases. The patient is generally placed on her back and delivery accomplished by the resident assistant. The forceps used is either the Elliott or the Simpson axis traction. Chloroform or ether is sometimes administered.

Catheterization is considered an evil. The nurse is expected to get along without it. They want no catheter epidemics. They have had no cases of cystitis due to the use of the catheter in 1250 cases recorded. The catheter is used about once in fifty cases (not including catheterizing before operative procedures or in cases of eclampsia). The bedpan is in certain cases placed under the patient and left there for some time, the nurse going to another part of the ward. It frequently happens that the patient is unable to micturate while the nurse is watching her, but does so after she is left alone. The last resource is to administer a copious enema, after which the urine generally comes while the bowels are being evacuated.

The placenta is generally expressed by the modified Crédé, or what is commonly known in Canada as the Dublin, method. The uterus is watched for fifteen minutes with the left hand over the fundus. Efforts are then made to squeeze the placenta out by grasping the fundus with thumb and fingers of one hand, or sometimes with two hands. This can generally be better accomplished with the patient on her back. If the placenta cannot be expelled in thirty to forty-five minutes, the hand is introduced into the vagina or uterus and the placenta is extracted. The operator is again expected to thoroughly cleanse his hand before such introduction. In the cases under his care a douche is not administered after such procedure unless some bad symptoms appear.

In the whole number of cases reported

only one instance of mastitis with suppuration occurred; and in this patient it was thought that mastitis existed before labor. The nipples are carefully watched, and if they become sore are washed after the child nurses with a carbolic solution 1 to 40, after which the following is applied, as recommended first by Hirst, of Philadelphia: Castor oil and bismuth subnitrate, equal parts. If the breasts become uncomfortable or painful from distention a binder is carefully applied. They use what is generally known in New York as the "Murphy binder," or the Snively modification of the same. They are now introducing the Y-bandage (Boston Lying-in Hospital), which has been very satisfactory to the writer in private practise in certain cases. Where they wish to prevent the secretion of milk—as, for instance, when the babe is still-born—they depend entirely on the Murphy binder, which is applied rather tightly, generally the day following labor.

Morphine administered hypodermically subdues most quickly the excitability of the nerve centers in convulsions.

Chloral hydrate is the best remedy to prevent recurrence of convulsions after they are to some extent brought under control. It is also sometimes useful as a preventive remedy when the symptoms of toxemia are severe and convulsive seizures are feared, but have not yet appeared. Wright sometimes combines the two remedies for severe convulsions, giving the morphine hypodermically and the chloral by enema. Chloroform sometimes has a good effect on the convulsions, but its administration has frequently disappointed him. There is no doubt that bleeding in properly selected cases has a good effect. We neglect it too much in these modern days. The writer has had but little experience with veratrum viride, and where he has seen it administered has not been favorably impressed with the results. He only mentions pilocarpine to give it an unqualified condemnation, as he considers it both uncertain and dangerous.

The author has not space to discuss the important subject of the induction of abortion or premature labor. He objects strongly to the former (except in extreme cases), and he does not hurriedly resort to the latter. In the 500 patients to which he has specially referred there were twenty-one cases of toxemia, with five of eclampsia. They induced premature labor twice, and assisted labor by digital dilatation of the cervix and the use of forceps in three instances.

*THE TREATMENT OF TUBERCULAR PERITONITIS BY ENEMATA OF COD-LIVER OIL WITH CREOSOTE.*

The great favor in which creosote is now held in the treatment of tuberculous conditions induced THOMAS (*Rev. Méd. de la Suisse Romande*, Nov. 28, 1897) to employ it in enemata of cod-liver oil in the treatment of the peritoneal form of this disease. The results which he has obtained, both in the disappearance of local symptoms and the general improvement in the health of the patient, are very satisfactory and would lead him to believe that a further study of this method, both experimentally and chemically, would be of great benefit.

The treatment consisted in the daily evening employment of an enema made up of an emulsion of 100 grammes of cod-liver oil containing one-half to two grammes (eight to thirty grains) of creosote, according to the age of the patient, with the addition of a few drops of laudanum to produce tolerance.

If the intestine has been previously suitably cleansed, there is no difficulty in retaining the enema, which is for the most part absorbed by the intestine, the amount discharged the following morning decreasing gradually as the treatment progresses.

*SEVERE SYPHILIS TREATED BY THE METALLIC IODINE.*

BOUYEYRON (*Lyon Médical*, No. 2, 1898) points out that iodine does not receive the recognition which its merits justify, due to the fact that it has not been used in sufficient doses and that the prescriptions containing it have not been properly compounded. The excipient should not combine with the iodine, should dissolve it perfectly, should correct its caustic property and its styptic effects, and should inhibit the combination of the iodine with the contents of the alimentary canal. Each dose should be given half an hour before meals. The ideal prescriptions, he holds, are as follows:

♢ Metallic iodine, 15 grains;  
Potassium iodide, q. s. ad solution.

♢ Neutral glycerin, 1½ to 3 drachms;  
Citric acid, 4 drachms;  
Simple syrup, 2 pints.

A teaspoonful is taken half an hour before meals, twice daily, until six teaspoonfuls a day are administered, or even twice this quantity. In thirty cases, iodism was noted in only two. In one case suffering from gummata of the legs and unable to take

either iodide or mercury, the administration of iodine was followed by cicatrization in fifteen days. The second case, presenting laryngeal pulmonary and cerebral symptoms, all pronounced, persistent, malignant and progressive in spite of ordinary specific treatment, recovered promptly under the iodine. In the third case, presenting tertiaries in the most malignant form, the iodine was equally successful.

*THE CURETTE AFTER ABORTION AND DELIVERY.*

BÖTTNER (*Centralblatt für Gynäkologie*, No. 51, 1897) has observed twenty-eight cases where the operator was Glævecke. He finds that the use of the curette is free from danger if carried out with proper precautions. It permanently stops hemorrhage after abortion or delivery, and as a rule the catamenia return soon, and continue normally, contrary to what is so often seen in mismanaged cases. A skilful use of the curette likewise prevents those morbid changes which are the cause of sterility.—*British Medical Journal*, Jan. 22, 1898.

*THE CELLULOID BANDAGE.*

The *modus operandi* of applying this bandage is as follows: Sheet celluloid is cut into small pieces and dissolved in a close-stoppered bottle in acetone, enough of the fluid being used to rise four times as high in the bottle as the celluloid. This solution of celluloid is rubbed into each layer of the gauze or crinolin bandage or jacket, an ordinary kid glove being worn for the purpose, as the celluloid otherwise dries on the skin and can only be washed off by acetone. For a jacket, at least ten layers are necessary; for a bandage, from four to six layers, according to the strength required. The outer layer is smeared with a coating of celluloid, which forms, when dry, a highly polished surface. It takes three or four hours for a celluloid bandage to dry. That is considerably longer than is the case if plaster of Paris is used. In order to permit of ventilation, small holes may be punctured in the jacket wherever necessary. Surgeons who have experimented with celluloid as a substitute for plaster of Paris in bandages report that the weight of such a bandage is less than one-fourth that of a plaster of Paris one, and less than half that of one stiffened with water glass. It is said to be not very expensive. According to Landerer, a jacket should not cost more

than \$1.50, which is no real objection to its use when one considers that, if well made, it will last for months and presents the further advantage of a smooth surface readily cleansed, and that it is impervious to urine and other discharges.—*Journal of the American Medical Association*, Nov. 20, 1897.

#### SOME CONSIDERATIONS OF ABDOMINAL INCISIONS.

WOOLSEY (*Annals of Surgery*, January, 1898) in studying this subject emphasizes the following conclusions as among those which may be drawn from the above considerations:

1. That abdominal incisions, except those in or close to the median line, should be obliquely transverse in order to parallel the nerves (and thereby also the cleavage lines of the skin), so as to avoid partial paralysis of the muscles, weakness of the abdominal wall, and a tendency to hernia.

2. That intermuscular or even transmuscular incisions should be preferred to those in the linea alba or semilunaris, for in both the latter cases the cicatrix is less strong and more prone to hernia, and in the semilunar line the nerves are necessarily divided.

3. That in place of the median vertical incision near the inner margin of the rectus, the trap-door incision around this inner margin offers many important advantages.

#### THE ELECTRICAL TREATMENT OF URETHRAL STRICTURE.

DEBEDAT (*Arch. d'Elect. Med.*, November, 1897) has introduced a modification of Newman's electrical bougie for which he claims especial advantages. Instead of being wholly metallic, the new instrument is covered with ivory up to its olivary extremity, so that the current passes to the urethra through this part alone. The author uses it in such manner as to produce dilatation without the passage of a current during its introduction, and electrolysis only while in contact with the stricture in the act of withdrawal. The electrical application is thus accurately limited to a small area. Debedat reports the successful use of the bougie in a number of cases, two of which he summarizes. He concludes that electrolysis by this improved method is a truly curative procedure as regards urethral strictures, which are by it attacked alone without injury to the healthy urethra. None of the cases hitherto observed

have called for further surgical treatment. In his opinion, moreover, there is a certain proportion of cases in which electrolysis is the method of election.—*British Medical Journal*, Jan. 22, 1898.

#### FORCED REDUCTION OF LATERAL CURVATURE OF THE SPINE.

NOBLE SMITH (*British Medical Journal*, Jan. 8, 1898), in a paper on this subject, states that the forced reduction of curvatures of the spine, a treatment which during recent months has attracted so much attention, has been chiefly directed to the correction of the deformity in caries, and (as far as this country is concerned) little notice has been taken of its application to cases of lateral curvature. Many cautious surgeons hesitate to run the risk which apparently exists when attempts are made to tear asunder inflamed and ulcerated vertebræ with the object of getting rid of the deformity in caries, but no such risk, the author thinks, appertains to manual force applied to scoliotic spines.

A young man aged seventeen was sent to the author on September 1, 1897, by Dr. W. J. Foster, of Reading. He first began to fail in health at the age of seven, and the spine subsequently gave way. At the age of thirteen he suffered from severe rheumatism. A year ago it was noticed that the right shoulder was projecting backwards. Recumbency was advised, an inefficient apparatus was applied, and the spine had been getting worse ever since. There is a family history of phthisis.

On September 7 the author applied force to the curve. The patient was placed prone upon a couch, the level part of which supported the chest, abdomen, and pelvis, the legs sloping downwards to a foot-rest. The surgeon stood over the patient and applied almost as much pressure as he could exert with his right hand upon the prominent dorsal curve, while with the left hand he supported the patient's shoulder in the contrary direction. The pressure was made downwards as well as to the patient's left, with the object of rotating the spine towards a normal position. In making this movement the ribs on the left side were seen to assume a more natural position, partly filling up the great hollow of that region. The spine was thus considerably straightened. The patient felt sharp pain at the time of pressure, but this went off in a few moments. The surgeon then applied a light apparatus to keep up the improvement produced.

On September 16 the patient reported himself as feeling much better in health, and stated that he could sleep quite comfortably in the appliance. The author again applied force in the same way as before, with the same result—that is, the spine was made distinctly straighter. The following week he again reported himself as feeling much better and stronger, and force was again applied, with a result similar to that following the former treatments.

In making these forced reductions something was heard and felt to give way, like the breaking of adhesions.

This patient was very plucky and was able to bear the operation without an anesthetic, but it is probable that the majority of patients would be more easily dealt with while under the influence of gas or ether.

In estimating the benefits likely to be derived from this method of treatment, the author has found that whatever position can be attained by apparatus can always be reckoned upon to become permanent in the course of time.

#### APPENDICITIS DURING AND AFTER PREGNANCY.

VINAY (*Lyon Medical*, Jan. 2, 1898) records four cases, and in all refers to thirty-two cases. The small number tends to show that pregnancy does not set up torsion of the appendix or colitis, conditions which would increase the virulence of the colon bacillus, and so induce appendicitis. In the thirty-two cases there were ten deaths, a percentage of thirty-one, which is much higher than that of Armstrong in his series of 517 cases, with a mortality of 12.8 per cent. The only complication of importance in appendicitis occurring during pregnancy is abortion, which was noted in forty per cent.; this accounts for the fact that in half the thirty-two cases the children died. This frequency of abortion is much above that seen in other infectious diseases, and is referred to the intimate vascular and lymphatic connections existing between the appendix and the uterine adnexa. Clado described an appendicular ovarian peritoneal fold as being constantly present, and considers that this carries the lymphatics from one to the other. Laforgue, however, only finds it in twenty per cent. of bodies examined. In two of Vinay's four cases the appendicitis was primary, but in the other two the appendicitis was due to the spread of infection

from the uterus. In the first there was post-puerperal infection which lighted up old appendicular mischief. The appendix was resected, and the right tube and ovary appeared healthy. In the other case, a primipara with a history of membranous colitis, there was hemorrhagic metritis due to retention of placental tissue, with subsequent appendicitis. The differential diagnosis of appendicitis during pregnancy from tubal gestation on the right side is not difficult, but it is less easy to distinguish it from right salpingitis complicating pregnancy. Appendicitis during pregnancy should be treated like ordinary appendicitis.—*British Medical Journal*, Jan. 22, 1898.

#### ECHINOCOCCUS OF BOTH LUNGS TREATED SURGICALLY.

STEINER (*Centralblatt für Chirurgie*, No. 1, 1898) relates a successful case with very severe symptoms. The heart was much displaced to the right, and when the mouth was opened a buzzing noise was heard synchronous with the cardiac sounds. On puncture of the left side of the thorax posteriorly, fluid containing hooklets was withdrawn. A year and a half before this report Professor Israel opened over a hepatic swelling, incised a large hydatid sac, fixing its edges to the abdominal wound, and then found a second sac behind it; this was opened and the sub-phrenic space discovered posteriorly. The seventh and eighth left ribs were resected behind, the costal and pulmonary layers of the pleura united by a circle of sutures, and the lung laid open within the circle. A hydatid as big as a normal human bladder was removed, lung immediately filling its place. At once the buzzing noise, caused by pressure of the cyst on the pericardium, disappeared. Six weeks later there was pricking pain and dulness at the right base. On puncture hydatid fluid escaped; dyspnea followed till the patient coughed up much hydatid fluid. Later on chronic bronchopneumonia developed. On recovery it appeared that the echinococcus had atrophied and come away. The patient is now well. Professor Israel noted that the right thorax, which had been treated by nothing more radical than puncture, was somewhat diminished in capacity, whilst the left, where resection and removal of a hydatid had been so successfully undertaken, remained of normal capacity.—*British Medical Journal*, Jan. 22, 1898.

*A PRELIMINARY REPORT UPON THE  
EXAMINATION OF THE BLADDER  
AND THE CATHETERIZATION OF  
THE URETERS IN MEN.*

In the *Annals of Surgery* for January, 1898, HOWARD A. KELLY publishes the following:

When the author first succeeded in his vesical and ureteral examinations in women in the spring of 1893, he expressed a conviction that he has often restated since then, that the bladder in the male could also be investigated in a similar manner, and in all probability the ureters could be catheterized. So positive was his conviction that he had a long, straight, male cystoscope made November 18, 1893.

Much as he desired to do so, it had been impossible for him to test this instrument until quite recently, owing to the excess of his regular professional obligations always crowding him for time, as well as to the fact that such men as did come under his care were private patients, and although suffering with renal diseases in some instances, he was not at liberty to pursue any line of investigation which might justly be called experimental. He also placed an instrument more than two years ago in the hands of his colleague, of the Johns Hopkins Hospital, who used it to examine the bladder in a case through a perineal section; but the instrument was not further tested through the intact urethra owing to the fact that the Casper electric cystoscope was already established in the male genito-urinary department, and its use well understood.

The author succeeded in securing a patient and testing the method of direct examination in the male bladder, through a simple straight speculum and under atmospheric distention induced by posture, for the first time on November 20, 1897, and he owes this opportunity to the courtesy of the surgical staff of the Johns Hopkins Hospital, and particularly to Drs. Harvey W. Cushing and Hugh H. Young.

The patient, a man about forty-eight years old, had a persistent hematuria of undetermined origin. After due antiseptic precautions and washing out of the bladder, it was filled with a saline solution and then examined with the Casper cystoscope. For the most part the bladder-wall was found normal, but at the base a dark, tufted, villous area was found from which a cloud of blood kept rising and mingling with the clear medium. The conclusion was reached that this was probably a vesical papilloma.

The bladder was then emptied with a catheter and the patient placed in the knee-breast position, with the chest close down to the table, the elbows spread apart, and the thighs slightly drawn up under the abdomen. The straight cystoscope, eight millimeters in diameter, and with a tube eighteen centimeters long, with a funnel-shaped opening and a diminutive handle like those attached to his first cystoscopes used in women, was then introduced. This cystoscope, made for him in November, 1893, was inserted into the bladder by Dr. Young without difficulty, while the patient was still in the dorsal position; when he assumed the knee-breast position the obturator was drawn out and air at once entered the bladder. The author attempted to let air into the rectum in order to drop the base of the bladder down more into the plane of vision; but little went in.

The examination of the bladder was now conducted by looking into it through an ordinary head mirror, reflecting an electric light which was held close to the sacrum. The base of the bladder came perfectly into view, and the posterior walls were readily seen. The sound mucosa of the posterior wall showed the characteristic pallor, with small vessels branching out here and there over its surface. We were able to see at once that the base was simply coated with blood which had accumulated there in the most dependent position, and that there was no papilloma or other growth present. The trigone and the interureteric ligament were injected and plainly defined.

The author was enabled to see and to demonstrate the orifice of the left ureter and to introduce into it one of the metal catheters which he uses in women. While the speculum was held up against the ureter, drops of urine trickled out of it down the tube of the speculum, and collected on the edge of the funnel. The urine was claret-colored, demonstrating at once the renal source of the hematuria. He could not introduce one of his long flexible renal catheters into the ureteral orifice, as he was unable to control the end of the catheter through the long, narrow speculum.

The examination was rendered difficult throughout by the insufficient control of the instrument afforded by the small handle; he also found that the tube of the speculum was longer and a little smaller than necessary.

It is a satisfaction to the author to be able to show in this report that his expectations have been realized, and he hopes at a later

date to present a fuller account of the methods of examination, with a description of a variety of better instruments for the purpose of exploring and examining the bladder in men. If we can succeed in doing away with the electric cystoscope by substituting a simple, direct method of examination for an expensive, complicated, and even dangerous instrument, the gain will be great. His direct method of examining also admits of direct methods of treatment. He could, for example, have cut or burned through the pedicle of a papilloma at the base of the bladder with almost the same facility with which he was able to inspect it.

#### THE TREATMENT OF HEMORRHOIDS BY INJECTIONS.

The treatment of hemorrhoids by the injection of carbolic acid and glycerin, mixed in various proportions into the substance of each pile by means of a hypodermic syringe, was first used by American surgeons. S. G. SHALEETA, of the Kieff Jewish Hospital, in a reprint from the *South Russian Medical Gazette*, Nos. 18, 19, 20, 21, 22, 23, 24, 1897, has modified this method by using pure liquid carbolic acid, injecting each pile with a Pravaz syringe to a certain degree of fullness, and completing the operation in one sitting. Two, three or four syringefuls of the acid are injected according to the number and size of the tumors. For external piles, he uses a mixture of two parts of pure carbolic acid to one part of a two-per-cent. solution of cocaine. Even if four syringefuls of this mixture are injected the quantity of cocaine is not sufficient to cause dangerous symptoms. As a matter of experience only a few drops should be injected where we have to deal with external piles, the syringe being introduced through the mucous membrane, and not through the skin. The history of sixty-nine cases treated in this way is given, and the results in all cases were highly encouraging. When the piles shriveled up and separated, the surface presented was similar to that produced by the operation for ligature or the clamp and cautery.

The advantages which the author claims for this mode of treatment are: (1) Absence of marked pain during the injections; (2) no necessity for anesthesia (this is a great advantage in old and feeble patients, and those exhausted by repeated hemorrhages); (3) little risk of suppression of urine following this operation; (4) no loss of blood during

the operation; (5) no necessity to keep the bowels quiet for three or four days after the operation, as is the case in other methods of operating.—*British Medical Journal*, Jan. 8, 1898.

#### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A., M.D. OXON., M.R.C.P. LOND.

Influenza has again awakened from its temporary slumbers, and has reasserted itself in a mildly epidemic form in the metropolis. At present it is curiously localized to the outskirts and has not visited central London with any degree of severity. For all our talk of a specific microbe, each year finds us as ignorant of the origin and of the prevention of the pestilence "that stalketh in darkness." This certainly cannot be attributed to any lack of facilities for investigation of the disease, for it has never been completely absent from the metropolis for close upon ten years, and during this period has seldom omitted an annual recrudescence. Even the prevalent belief that its ravages are in some degree favored by mildness of season is a matter of considerable doubt. It is true that most of the epidemic extensions have occurred either in mild winters or in spring, but a notable exception was the severe outbreak in the spell of severe winter which will long be associated with February and March, 1895. However, while we are totally in the dark as to what is influenza and what it is not, we obviously cannot derive any useful information from mortality statistics. In the face of an epidemic of influenza it is impossible to decide how much of the mortality from diseases of the respiratory system is influenzal, and how much is of other catarrhal type. Certainly there is much too great a tendency to lay the whole category to the charge of influenza. Autumn has invariably been the period of greatest immunity, and next to autumn summer. This would suggest a microbe with a maximum fertility at a temperature intermediate between the lower ranges of winter cold and the higher ranges of summer heat. Last week a slight abatement of the death-rate gave a promise of better things, but unfortunately this has not been confirmed by the returns of the present week. Whilst medical

men are at their wits' end for some drug with a semblance of curative power, the lay public are never at a loss for an infallible remedy. This year it is phenol that has cured every one who has consented to try it. For some reason or another the mildly innocuous eucalyptus has never been dethroned from its high position in popular favor. I fancy the charm must be in the manifold modes of administration. It has been offered to me on sugar, on my handkerchief, on sawdust in a saucer, and I have even walked to my bedroom through a grove of eucalyptus trees.

A case of arsenical neuritis shown by Dr. Colman at the Clinical Society of London suggests some points of therapeutic interest. Briefly, the history of the case was as follows: From September 27 to October 28 (with the exception of six days, when the treatment was intermitted because of gastric disturbance) the child took fifteen minims of Fowler's solution three times a day for the cure of chorea. The chorea was cured at the end of that period, and we may charitably assign the cure to the heroic doses of arsenic. On November 10, however, she complained of weakness and tingling of the legs, and in the course of another week distinct foot-drop developed. In December, on readmission to hospital, there was complete paralysis of all the extensor muscles below the knees, with well marked reaction of degeneration. There was no alteration of cutaneous sensibility, but great tenderness of the leg muscles. There was well marked arsenical pigmentation in the neck and groins. By January 14 the child was rapidly recovering, having been kept in bed and treated with massage and electricity. That this was no special idiosyncrasy of the patient was borne out by Dr. Colman's statement that he had seen several such cases before, and other members had had a similar experience. It is interesting to note the period that elapsed between the cessation of the drug and the appearance of the symptoms. The therapeutic value of the case is that it sounds a note of warning against the heroic doses of arsenic, which are incautiously employed in the treatment of chorea. The small experience that I myself have had with these large doses has certainly discouraged me from resorting to them again. In one case a child of seven years was seized with violent colic after the first dose of fifteen minims, and I am half ashamed to admit that her chorea was cured by the single dose. In most cases, however, I have found no benefit from large doses, and much the same

might be said of smaller doses. One wonders how arsenic succeeded in establishing itself as almost a specific for the cure of chorea. Peripheral neuritis is hardly likely to be of common occurrence from the medicinal use of arsenic, because gastric derangements usually indicate that the limits of tolerance have been reached, and lead to remission of its use. The patient in Dr. Colman's case was a girl twelve years of age.

In the *St. Bartholomew's Hospital Journal* Dr. Lauder Brunton discourses pleasantly on the subject of exophthalmic goitre. The main difficulty in rational therapeutics is to disentangle the symptoms which may be due to increased internal secretion from those that are due to primary nervous derangement. We quite agree with Dr. Brunton that the primary cause of the disease must be looked for in the higher central nervous system, but we would rather look in the neighborhood of the centers of emotion than about the medulla, as he suggests. Filehne's experiments on the testiform bodies have long since been discredited by a repetition of these experiments by Ferrier, in which none of the symptoms of exophthalmic goitre ensued. Moreover, the verdict of clinical experience is notoriously in favor of such general measures as promote rest and tranquillity of mind and body, aided by such drugs as restore tone to the disorganized nervous system. Most physicians have exhausted their patience and their repertoire of drugs in the attempt to alleviate some or other of the more obvious symptoms of the disorder, and ultimately fall back on such general remedies as we have indicated. Dr. Brunton speaks with some degree of certainty of the existence of increased secretory activity of the thyroid gland. This is hardly in accordance with what is found in glands that have been removed either by operation or after death. It is true that the secreting surface of the vesicles of the thyroid is very markedly increased, but my own experience of some dozen glands has been that the secreted substance in the vesicles is remarkably diminished; and this has been confirmed by many other observers. Also the injection of thyroid extract into the circulation produces an effect on the heart and vessels exactly opposite to that which we find in exophthalmic goitre. Such injections lower blood-pressure by increasing the calibre of the arteries without any obvious effect upon the heart. Lauder Brunton speaks hopefully of suprarenal extract in the treatment of exophthalmic goitre,

exerting as it does so powerful an influence on muscle tissue in general and particularly on the muscle of the circulatory system. He himself had seen good results from its employment in a single case. Of course in a disease which is so liable as exophthalmic goitre to periods of temporary improvement apart from any treatment, it must needs be fallacious to draw any conclusions from a single case. We have ourselves been signally disappointed in several instances, and we fancy that this is the general experience. All the animal extracts in turn "have their day and cease to be." Thyroid extract was employed for a while by physicians in defiance of their belief in a thyroid toxemia, and now and again recoveries were reported. Then thymus extract was given a trial, accidentally in the first instance, and passed through the same stages of promise and disappointment. Quite recently Dr. Hector Mackenzie has shown pretty conclusively by a tabular statement of results that we can look for little or no assistance from thymus extract. We conclude that suprarenal extract will shortly go the way of its predecessors. There is, however, still in this country a great disinclination to throw the toxic theory overboard, and as yet no one has been found to attack the cervical sympathetic on the lines laid down by Jaboulay and Abadie.

The Royal Medical and Chirurgical Society has followed up its discussion on the Prevention of Enteric Fever by another discussion on Immunity and Latency after Operations for Reputed Cancer of the Breast, which promises to be of some interest, as most of the leading London surgeons are taking part. The discussion was opened by Mr. Marmaduke Shield, who satisfied his audience (1) that operative interference was justified by the amount of cases in which recovery was complete, and (2) that even by the old-so-called "incomplete" operation the results were very much better than was generally supposed. For the rest the discussion drifted very much into an apotheosis of the "incomplete" method by the older surgeons as against the "complete" method—Halsted's operation—as commonly practised by the younger generation of surgeons. Mr. Bryant objected to the term "incomplete" as suggesting some omission on the part of the surgeon. He believed that the mortality from the method of clearing out the axilla and removing the pectoral fascia in every case was greater than that of the more limited method, the operation being too ex-

tensive for old subjects to endure. Whether this be the fact or not, there can be little doubt that such would have been the case prior to the introduction of antiseptics. Mr. Bryant also objected to the completer operation on the ground that recurrence was often not in the axilla nor in the line of the lymphatics; but though this may occasionally be the case, there can be no doubt, as Mr. Watson Cheyne has conclusively shown, that in the large majority of cases recurrence does occur along the routes of lymph flow, and that the best way to prevent this is by removal of the axillary glands, of the pectoral fascia, and more or less of the pectoral muscle. The objection to interference with the pectoral muscle is the subsequent limitation of the movements of the arm, but Mr. Butlin was inclined to attribute this more to the condition of the integument than of the muscle. It is difficult to define what "cure" is. Many of the speakers objected to Volkmann's three-year limit as the test of cure, because recurrences had taken place at greater periods of time. But after all the essential question is the prolongation of the patient's life, and it would be cruel to advise an operation that held out a good prospect of an extended term of years, even in face of the possibility of a later recurrence.

A good deal of discussion has been devoted lately to the dangers and uses of erythrol tetranitrate, which not long since was recommended by Bradbury for relief of the paroxysms of angina pectoris. An accident has recently occurred from the explosive property of the compound. Like other polyatomic organic nitrates, the erythrol tetranitrate detonates when roughly struck, but Bradbury states that it can be rubbed up in a mortar without danger, if ordinary care is used. The melting point of the substance is 142° F., and it does not undergo decomposition at this temperature. To produce explosion, it must be rapidly heated to a much higher temperature. In the case alluded to erythrol tetranitrate was combined with lactose, and Bradbury attributes the accident to its union with a readily oxidizable substance. Martindale has supplied a good deal of useful information as to the pharmacy of the drug. He found that it could be readily exploded by striking it after heating it to 130° F. Like nitroglycerin, it is soluble in fats and oils, and for the preparation of tabloids a stable solution could be obtained in the fat of chocolate. Neutral fats and oils when gently

warmed dissolve one-fourth of their weight of erythrol tetranitrate, but on cooling some of the substance crystallizes out. The chocolate tabloids do not detonate, as the fatty coating appears to act as a protective, and if an excess of fat be used, they can safely carry a considerable amount of the crystals. Martindale summarizes in a letter to the *British Medical Journal* the conditions in pharmacy that render the tetranitrate more explosive as follows: (1) He finds that if a little be heated on platinum foil it deflagrates with a flicker; (2) a trace triturated violently in a porcelain mortar does cause slight explosions; (3) mixed with a little lactose he could not explode it by striking it with a hammer at ordinary temperatures, or even after moistening the mixture with spirit; (4) a trace of an oxidizing agent such as silver oxide, mercuric oxide, potassium permanganate, potassium chlorate, or potassium nitrate, as well as reducing agents such as reduced iron, charcoal, hypophosphites, pyrogallol, morphine, and creosote, all seemed to render erythrol tetranitrate more explosive by concussion.

Abundant evidence of the therapeutic efficacy of the drug is forthcoming; indeed, in some cases it appears to be more persistently effective than nitroglycerin. The tabloids are more or less pungent to the tongue. The moral of the unfortunate accident is to deal gently with preparations of erythrol tetranitrate.

In the January number of the *Practitioner* there will be found some useful remarks by Sir William Broadbent on the Treatment of Dilatation of the Stomach. When the stomach tube is used, as it always should be when there is such accumulation of contents as to lead to copious vomiting, he suggests that the best time for using it is the evening, as it helps to secure a night's rest. Beyond the usual dietary restrictions for the relief of gastric distention, he recommends a tumblerful of hot or cold water night and morning, and half an hour before the principal meal. The hot water seems to stimulate the muscular coat of the stomach to contract so as to expel the gases that stagnate and passively distend the stomach. He finds the most suitable beverage in many cases one or two tablespoonfuls of brandy or whiskey in a claret glass of hot water towards the end of lunch or dinner. Of drugs for relief of overdistention he highly recommends a combination of sodium bicarbonate 20 grains, sodium sulphocarbonate  $7\frac{1}{2}$  grains, tincture nux vom-

ica  $7\frac{1}{2}$  to 10 minims, with sal volatile, tincture of chloroform, and peppermint water, or other carminative, three times a day, rather nearer the next meal than the last, morning, afternoon, and near bedtime. This he replaces in a few days by an acid tonic with pepsin taken immediately after meals, retaining the evening dose only of the alkaline carminative. As the dilatation yields to treatment, measures should be set in train to deal with the catarrhal condition of the mucosa, or the atony of the muscular coat that has been the cause of the overdistention. When the atony is part of a general neurasthenic condition he advises a pill containing arsenous acid and sulphate of strychnine, one-twenty-fourth grain of each, with extract of calumba, gentian, or anthemis, with papain or pepsin if necessary, and rhubarb or aloin if constipation is present. Treatment of gastric dilatation may often be conveniently initiated by moderate purgation with calomel or blue pill combined with colocynth or rhubarb.

---

#### BERLIN LETTER.

BY JAMES J. WALSH, PH.D., M.D.

---

The most interesting thing in therapeutics in Berlin for some time was the announcement that a department for the treatment of rabies by the Pasteur method was to be added to the Institute for Infectious Diseases here. Medical sentiment generally at Berlin, under the lead of Professor Koch and his school, has always looked with disfavor on the Pasteur treatment. The rest of Germany takes its cue, to a great extent at least, from here, and so while the English had come to acknowledge the value of the treatment, and the Italians had taken it up, and finally the Russians were enthusiastic over it, medical opinion this side of the Rhine would not listen to it at all.

It is the late International Congress, or rather their visit to the Russian institutions, that seems to have finally convinced the Germans that they were perhaps obstinately opposing a great therapeutic method. The discovery and development of the treatment of rabies by the injection of the desiccated spinal cords of rabbits, in whom the disease has been produced by inoculation, is absolutely empiric. It is absolute empiricism, too, in that domain where self-deception, if we are to read medical history aright, is easiest—the realm of applied therapeutics. No wonder that the carefully scientific Koch, and

the long since therapeutically disillusioned German medical mind, should have opposed. But the wonderful intuition of the genius of Pasteur seems to have led him aright through even the uncertain mazes that lead to a new biological therapeutic method.

The Russian statistics in the matter seem to prove beyond a doubt the efficacy of the treatment. They are the most favorably situated for observations, since lyssa is endemic among the wolves of the vast plains of the south—the Russian steppes. Their bite gives rise to the most virulent and rapidly fatal form of the disease. Their well known habit of jumping at the face of their victims gives the most fatal form of hydrophobia known; the richness of the lymphatic absorbents here, and the closeness of the nerve centers, where the virus of the disease is known to be reproduced, constitute most unfavorable factors for the prognosis of these cases. Yet it is from such cases that the Russians have gathered their favorable statistics.

The department for the Pasteur treatment here is said to be only experimental as yet; an appropriation of only about \$1000 is made for it. It is clear, however, that the principle of the treatment is admitted and its importance acknowledged. A corresponding revolution in medical opinion can be looked for now confidently throughout Germany and among those for whom German medical thought is the only representative of what is best in medicine. This will include, I suppose, a number of American skeptics as to the Pasteur method.

Professor Heubner, the distinguished professor of children's diseases here, said some interesting things in a talk on the serum therapy of diphtheria the other day. The children's wards at the Charité, like most of the rest of the old hospital, are extremely unhygienic. They were never meant for modern medical methods at all. Perfect segregation is almost impossible owing to the arrangement of the buildings. As might be expected, children's diseases easily became epidemic. Diphtheria contracted in the hospital was of rather frequent occurrence. Some time ago Professor Heubner began to give prophylactic injections of diphtheria serum to all the children under his care, for the purpose of keeping them immune to the disease. This was continued for nearly six months, with only one suspicious case observed that originated in the house. That had very light symptoms as of an ordinary angina, and though the diphtheria bacillus

was demonstrated by cultures to be present in the throat, Professor Heubner is inclined to think it one of those cases where the almost ubiquity of the diphtheria bacillus allows of its demonstration, though it is not etiologically concerned in the condition under observation; just as, after all, it has been found by such distinguished observers as Raux and Yersin in perfectly normal throats.

After a while objection was made to this wholesale injection of diphtheria serum, because it was unusual and smacked too much, to certain of the more conservative directors, of experimentation upon the little patients. The immunizing injections were accordingly discontinued. In six weeks three cases of undoubted diphtheria had developed in the wards, though needless to say every precaution had been taken to exclude it. Even the conservatives were convinced. The injections were resumed. They have had no diphtheria develop since, though that is months ago.

About 200 antitoxin units are given as an immunizing dose. The immunity conferred lasts, according to Professor Heubner's observations, almost exactly three weeks—twenty-one days being the average in a number of cases observed. The practical development of immunization here was bound up with all the more difficulties, because it is here that the famous Langerhans case occurred. The prophylactic injection of the child of Virchow's assistant was followed by its immediate death. No medical man now considers the serum to have been primarily responsible, but the case threatened to seriously disturb the advance of diphtheria serum therapy for some time. It is still so well remembered in Berlin that few families in private practise will, with a diphtheria case in the family, consent to the immunization of the other children, even though strongly advised to it by their attending physician. Professor Heubner says that he always recommends it now, and has had most excellent results from it. Gradually, he thinks, the prejudice will entirely disappear, as it has already in many families because of the success of immunization.

In Professor Heubner's clinic children with measles are always given an immunizing injection of diphtheria serum as part of the routine treatment. Since they have begun to do this, they have had none of the disagreeable and often dangerous cases of measles-croup, which occur so often in run down children.

As to the sequelæ and complications of serum treatment here they should be seen very often if anywhere. They are not frequent. Some children have an idiosyncrasy, however, and the injection of animal serum is followed by an urticarial rash. This may appear immediately after the injection, or not for two to three weeks, and is sometimes very obstinate to treatment. As the serum is made stronger—*i.e.*, as a smaller quantity of liquid is made to contain more antitoxic units, and so less and less animal serum has to be injected—these accessory effects of the serum become rarer and may be expected in this way eventually to entirely disappear.

Professor Heubner considers that Behring's expression some time ago, that 600 antitoxic units would be sufficient for any case, does not hold for very severe cases. Here they inject at least 3000 antitoxic units where lesser amounts fail to give relief in a reasonable time. Larger amounts, too, they have used, but as a rule where 3000 units does no good, higher amounts—6000 to 8000 units—also fail. Cells are so paralyzed in their functional activity by the amount of toxins present in such cases that even when these are neutralized by the antitoxin, the cells fail to regain their quondam function.

In the cases where the disease is already four to five days old when the injections are begun, the antitoxin is not the specific that it is when taken earlier, but there is no doubt that it does good. While they formerly saved only twenty-five to thirty per cent. of cases admitted to the hospital on the fifth day of the disease, the mortality of such cases is now not more than thirty per cent. altogether. In all cases other remedies besides antitoxin are used. In severe cases there are two special features in the therapy—the use of potassium iodide, ten to fifteen grains a day (what they consider here a large dose as a resolvent—*i.e.*, a membrane loosener), and sweating. A hot-air bath of three hours is given, followed by one hour's intermission; then three hours more. Professor Heubner considers this very efficient in relieving the system of toxins.

The antipyrin patent expires in July of this year, the limit of German patents being fifteen years and no renewals being allowed. It is thought that this will reduce the price of the drug by more than one-half. In the meantime a number of allied preparations have been made which have attracted considerable attention here. The last of these is pyramidon, and I have heard all of the prom-

inent clinicians at least mention it, while some of them speak very highly of it.

Antipyrin is composed of two groups of atoms, the benzol ring and what Knorr has called the pyrazolon ring. Attempts at substitution in the latter ring have been made which would retain all the effectiveness of antipyrin and yet avoid its depressing effect. In this last preparation (pyramidon) all of the O atoms of the pyrazolon ring are replaced by nitro-methyl groups, giving phenyl-dimethyl-dimethylamino-pyrazolon. This, it is claimed, owing to the absence of stable O radicals, is especially efficient, while clinically it seems to be but very slightly depressing.

---

#### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

The last two months have been marked by the death of two of the most eminent medical men in Paris—Tarnier and Péan. It would be hard to find two men more dissimilar in their most salient characteristics, Tarnier being essentially a man belonging to the Faculty of Medicine, scrupulous in his professional conduct, while Péan has always been somewhat of a free lance, as is indicated by his having been admitted to the Academy of Medicine only in 1887. Both men, however, owe a part of their reputation to their having invented instruments which are now universally known. Every one has heard of Tarnier's basiotribe, his special forceps, which though more complicated than Levret's is more physiological in its action, and his incubator for prematurely born infants. Péan's name is linked in like manner to hemostatic forceps, and to the various forms of the latter instrument which are used in abdominal surgery.

Péan was born in 1830 of well-to-do parents, his father being a miller of Châteaudun, a small town to the south of Paris. Tradition has it that his father, operated upon by a surgeon in Paris for some slight affection, was so much impressed by the size of the fee required that he then said to his son: "There is money to be made in this; take up medicine!"

Péan worked hard and was named first interne. His masters were Denonvilliers and Nélaton, with whom he stayed two years, and from whom he learned how to operate. While he was prosector of the hospitals, he gave instruction in surgery on the cadaver, and his energy and thoroughness have given

cause to regret that he did not follow up more the purely scientific part of surgery.

Once surgeon of the hospitals, Péan soon began a series of abdominal operations, which until then had been tabooed by the various scientific bodies. It was in 1864 that he performed the first successful ovariectomy in France. There were soon to follow a case of abdominal hysterectomy for fibroma, a splenectomy, and other operations of like nature.

Another point in technique which he applied brilliantly was what was described under the name of "morcellement des tumeurs," and which, applied at first to abdominal operations, was found to be of so much service later in the removal of the uterus by the vagina. Péan operated in a most masterful manner, and his calmness and astonishing rapidity have always been the subject of comment by those who saw him at work. He always wore a dress suit when operating, and it was really impressive to see him remove a tumor where there was much bleeding, and in case of hemorrhage quietly stop the flow of blood with one or two of his fingers.

Péan allowed his internes to operate, and considered them more as assistants than was the case twenty years ago. However, he made it a point to teach them in the first few months all that was necessary to insure their undertaking minor operations with ease.

In 1892, as he was obliged to leave the hospitals on account of his having reached the age limit, he established in the rue de la Santé the International Hospital, where he still kept on operating. He was in good health two weeks ago, but was taken ill rather suddenly with influenza and pneumonia, and died on the 30th of January, showing at the last the greatest calmness and resignation.

In a previous letter an account of the "affaire Laporte" was given, and it was stated that the defendant had been condemned to three months' imprisonment with application of the Béranger law, which consists in suspension of the penalty inflicted by the court until an ulterior condemnation. Pinard, the celebrated accoucheur, has continued his efforts in behalf of Dr. Laporte, and has obtained letters from various representative men in midwifery, which he has had published.

In medical science bacteriology is always prominent, and as usual one or two new bacteria have been studied or analyzed very fully. Dr. Achalme, of Paris, demonstrated

some time ago a bacillus which he discovered in patients suffering from rheumatic fever, and gave various means of differentiating it from other organisms offering the same morphology. Triboulet and Coyne have taken up the subject again and examined a certain number of cases of rheumatic fever with or without complications. They describe an elongated coccus, found in pairs, grouped in chains at times, presenting dimensions varying between 1.5 and 2  $\mu$ . This organism is characterized by its being anaerobic, is easily cultivated in bouillon or ascitic serum, is colored readily by thionine, but is not discolored by the Gram method. They look upon this germ as being the real microbe of rheumatic fever, whereas the bacillus of Achalme is to be found only in complicated cases. Their researches have, however, been criticized, and it has been objected that some varieties of staphylococci give the same reactions.

In an article published in the *Presse Médicale*, a paper recently started in opposition to the *Semaine Médicale*, so long the favorite journal of the medical practitioner in France, Dr. Landouzy, professor of therapeutics at the Faculty of Medicine, compares the relative value of antipyrin and quinine in the treatment of influenza. He begins by observing that the present epidemic of influenza in Paris is characterized by its asthenic and depressing forms, rather than by the painful ones seen in 1890. This special asthenia, which is so much seen, can prove dangerous or even fatal in old people, for instance, but if certain cases have proved more serious than others, it is sometimes due to an ill-timed use of antipyrin. It is unfortunately too true that antipyrin has come to be considered almost a specific in influenza, while it should only be looked upon as a means of alleviating pain. The result is that sometimes as much as two or three grammes of antipyrin are given. It would be unnecessary to call attention to this if this drug were incapable of producing untoward results, but it is only too well known that it depresses the nervous system, lowers the vascular tension, and produces peripheral vaso-dilatation, diminishes the oxidizing qualities of the blood, and by decreasing the blood-tension in the kidneys, lowers the quantity of urine excreted. It is thereby easily understood how pernicious are the effects of antipyrin, and how, far from helping the patient, its action is more or less similar to that of the disease. The moral

of all this is that antipyrin should not be considered as a drug specially indicated in influenza; what is really necessary is to strengthen the patient, to tone up his nervous system, so that alcohol, coffee, quinine, artificial serum are to be used.

Without exaggeration, Dr. Landouzy thinks that there are hardly any therapeutical indications that may not be fulfilled with quinine, the action of which is stimulating, tonic, and anti-infectious. As a conclusion Dr. Landouzy would choose quinine always, and only use antipyrin when obliged to do so.

Attention has been called of late to the use, or rather disuse, of those ancient therapeutic agents, bleeding, emetics, and blisters. Dr. Robin, agrégé at the Faculty of Medicine, speaks highly of them and considers that bleeding is certainly indicated in apoplexy, in some cases of pneumonia, and also where by a sudden depletion a certain quantity of toxins may be removed from the circulation, as in uremia. As for emetics, Dr. Robin has studied their action upon lung capacity, and the results of his investigations tend to show that respiration is notably increased, and the oxidation carried on in the body much more intense. Some care should be taken in the use of emetics with old people, but in certain cases of congestion or bronchitis they are certainly very useful. As for blisters, they would seem to affect the respiratory functions not so much by their chemical composition as by a reflex action leading to more intense muscular action in the respiratory muscles.

In surgery we must mention Dr. Chipault's communication to the Société de Chirurgie on scoliosis. The author considers that this affection should be treated somewhat as Pott's disease has been by Cabot. This treatment consists first of all in reduction by simple means, such as an apparatus for traction and extension, while lateral pressure is brought to bear gradually on the summit and extremities of the deformity. This removal of the deformity can be produced in successive stages or else accomplished forcibly under ether or chloroform narcosis, a course which is not recommended by Chipault. Once the scoliosis has disappeared, a plaster-of-Paris bandage should be applied similar to that used in Pott's disease, fitting well on to the body. In bad cases, various metallic hooks, similar to Malgaigne's hook, can be applied, and by their pressure on the bony projections they prevent a recurrence of the deformity. The result of this treatment would

seem from the author's statements to be most successful, and in Chipault's estimation much to be preferred to the very long and unsatisfactory treatment by gymnastics.

The treatment of burns by picric acid has been the subject of some controversy, and in the discussion which took place at the Société de Chirurgie, the general opinion was that it was no advance on the usual methods. Dr. Walther communicated two reports of poisoning by picric acid in children. Dr. Brun also cited a fatal case.

An uncommon affection which has called forth quite a number of observations, on the subject being communicated, is subphrenic abscess. Two cases were seen last summer by Dr. Courtois-Suffit at the Beaujon Hospital, and operated on by Dr. Lejars in Dr. Theophilus Anger's service. This disease, which used to be well-nigh fatal, offers at present a very much improved prognosis.

Dr. Courtois-Suffit states that the symptoms observed are those that are seen in pus formation, and moreover tympanism in the right epigastric region with tumefaction. This tympanism is replaced by dulness in its lower half, when the patient assumes a sitting position. This affection is caused by perforation of the stomach or duodenum.

The first case was operated on by incision on the right of rectus muscle and subsequent parietal suture, and was drained and washed out at first every other day. The patient recovered. The second case, a woman thirty-nine years old, was also operated on by Dr. Lejars. Though there was improvement the first two days, she died the third day, and on examination an abscess near the spleen communicating with the stomach was found. As to the abscess which had been opened, nothing had occurred to cause death. These abscesses differ from others of the same region by the fact that they are in communication with the stomach, which presents an ulceration. They should be incised freely, and the mortality has thus been much reduced.

---

#### ROME LETTER.

---

BY A. DILLON CARBERY, M.D.

---

With unexceptionable weather and the presence of an unusually large number of visitors, the season in Rome promises to be of the gayest; yet in spite of its attractions and the great sanitary improvements of the last ten years, the city still suffers, unjustly one

would think, from a legendary reputation for unhealthiness which prevents its recognition as an admirable health resort for certain classes of invalids.

We are always glad to note the gradual dissipation of old prejudices, and certainly the legendary unhealthiness of Rome is amongst those superstitions which it would be to the common weal to dispel. A recent publication of the scientific press, namely, Dr. Mendini's Hygienic Guide to Rome, translated and edited by Dr. John J. Eyre, who practises here, is a sparkling retort to the maligners of the Eternal City. So far back as 1870 Baccelli was earnestly laboring to put an end to what he calls "a calumny which struggled not only with truth, but with the divine beauty of our sky." Following in these worthy footsteps Dr. Mendini, by careful reference to sanitary reports and a clever summarizing of mortality returns, meteorological charts and scientific documents of a like nature, establishes the conclusion that Rome is not only healthy, but has undoubted merits as a health resort. Curiously enough, the author in his preface describes this conclusion as altogether unexpected, for the reason that he himself at the outset of his inquiries suffered from the common prejudice that the city was not completely healthy. Referring to this interesting little book, we find that Rome holds the premier place for sanitary merit amongst the cities of Italy, and although it cannot claim superiority over all the other large capitals, it certainly takes precedence of some. Thus, for the ten years 1884 to 1893 the death-rate from all causes in Rome exceeds that of London, Paris, and Berlin, whereas it is lower than that of New York, St. Petersburg, and Vienna. In 1895 the death-rate of the resident population was only 17.3 per 1000. As to the malarial myth, it is disposed of in a word by simple negation. Malarial fever does not exist in Rome. Dr. Mendini admits, indeed, that deaths from malaria do occur in the city, but "The deaths indicated in the statistics all appertain to the agricultural population, who contract the disease in the Pontine marshes and in the other mephitic plains of the Agro Romano, and afterwards are admitted for treatment in the Roman hospitals. Amongst the population resident in the city there is not a single death from malarial fever."

When in imperial times the plebs clamored for bread, the patricians would offer games in the Colosseum and gladiatorial fights as a

palliative; to-day, when the corner in flour maneuvered by the millers has led to riots and disturbances, and the great increase in the price of bread to an excitation of popular feeling which may at any moment lead to serious results, we are gratified here in Rome by a fierce encounter between Professor Celli of the Instituto Igienico and the Belgian Integral Bread Company. Weight against wit—a barbarian against a trained fighter from Urbino. The Belgian firm, offering whole meal bread at a much lower price than the bakers, is doing good business and intends to extend its operations, although established but a few weeks. From the first day of the opening of the bakery Professor Celli had condemned the bread on *a priori* reasons, stating that the antispire principle (which consists in disintegrating the cortex of the grain by a series of spiral knives interlocked) could never render the husk digestible, and that the bread was unwholesome. A violent polemic between the company and the professor was the result, in which the old controversies of whole meal or integral bread were all rehearsed. As a final note Celli published in the *Nuova Antologia* (the Italian "19th Century Review") a vigorous condemnation of the bread, which he described in the words of Vallin, of Paris, as good for dogs only, or vicariously for the constipated. Celli, who is undoubtedly a very earnest sanitarian, and as a deputy in the house is known to have socialistic leanings, explained to me in animated words the reasons for his action. Integral or whole meal bread, he says, is by secular tradition, universal experience, and in the light of modern research, wholly condemned, because, agreeing with Wiche, Menicanti, and Prausswitz, the husk of the grain is absolutely indigestible, as is the substance on the inner surface of the husk. The addition of these extraneous matters to the bread can be of no advantage and, acting as intestinal irritants, must prove harmful to the Italians, eaters of bread and fruit, amongst whom constipation is unknown and who would unquestionably lose much of the value of the food owing to its shorter stay in the digestive tract. Celli is persuaded that white bread is superior as a food to all other farinaceous comestibles, and with the addition to the paste of common salt and an acid phosphate (easily made by the baker) an ideal food is obtained. He further recommends as perfection bread made from a mixture of seventy-three per cent. wheaten flour, twenty-three per cent. flour from Indian

corn, and about four per cent. of flour made from beans. Celli's bread is palatable enough and highly nutritious, but has never been accepted by the proletariat for undefined reasons, possibly from the waywardness of nature that often dislocates useful from agreeable.

There has been of late a recrudescence of the old crusade against foreign medical men practising in Italy. As it stands, the sanitary law permits duly qualified practitioners of other nationalities to exercise their calling here, but only amongst their own countrymen, and it is forbidden to them to render any professional services to Italians. The question is not a new one. Twenty years ago an agitation was on foot to eject the non-Italian physicians, but it produced no practical result. Last spring a deputation of the delegates of the Order of Doctors appealed to the Minister of Public Instruction to formulate a project of law to alter Article 23 of the sanitary law under which hospitality is extended to our profession. To this demand the minister gave but little hope of ultimate satisfaction; and when the matter came before the Superior Council of Health it was deemed inexpedient to alter the statute, having regard to the possible economic loss which the country would sustain owing to a decrease in the influx of foreigners. Matters stood thus when the congress of the delegates of the Order of Doctors met here last October. At the first meeting the question was again raised, Santini, Bossi and others making a vehement attack on the foreign practitioners, whose numbers were stated as being 1500. It was proposed by Bossi that the government should be appealed to to cause a revision of the law in the direction of protecting the native practitioner and putting Italy on the same footing, in this respect, with the Continental powers. It was argued that free trade, though unquestionably beautiful in the abstract, was inferior to protection, where the latter was adopted by all the Continental nations. Some of the orators were more vigorous than academic in their denunciations of the "stranieri," but these were few in number and not from the ranks of the more worthy.

Durante, who is a member of the Senate, offered to carry the motion before the houses of Parliament, but as the voting, curiously enough, was not unanimous, he withdrew his proposal. A few days ago Santini, who is a deputy (the number of medical men in the

Italian houses of Parliament is large and they are a significant body) and who seems to be the principal instigator of the agitation, raised the question in Parliament. The Minister of Public Instruction answered the interpellation by demonstrating that the figure 1500, as representing the number of foreigners, was inaccurate, and that in reality they did not exceed 100 for the whole of Italy, concluding his remarks with the usual assurance that the matter would be attended to in the future. What will be done eventually it is impossible to surmise, but as in the domain of Italian politics the future is often illimitable, it is sufficient for us to note that the agitation exists, but that it is not actively fostered by the great heads of the profession nor encouraged by the Government. We should be the last to believe that the presence of the foreign physician adds an additional charm to the delights of sunny Italy, yet we may be pardoned in thinking that the residence here of the "free lances of Esculapius," as Santini is pleased to dub us, must do something to increase the popularity of Rome, at least as a health resort.

Away from these dusty polemics, the work of the schools and the studies of the laboratories proceed with calm and undisturbed tenor. Dr. Fiocca, of the Santo Spirito Hospital, gives us a simplified process for the serodiagnosis of enteric fever. He spreads a thin layer of fresh broth culture of the bacillus typhosus upon a cover-glass, and into this he conveys from a needle point the smallest quantity possible of blood procured from the patient under observation. Thus the amount of blood mixed with the culture broth is less than that recommended by Vidal. The cover-glass is then placed on a hollow slide, as for hanging drop specimens, and may be secured with vaselin. The reaction, says Dr. Fiocca, occurs within ten minutes, or at most from twenty to twenty-five minutes, never after thirty minutes, and it is complete when the characteristic bush-like grouping of motionless bacilli is observed. In the case where a few free moving bacilli are seen between the groups the reaction is considered to be also complete, though of course not so clearly, and the test regarded as confirmatory. The process is quite as reliable as that of Vidal, with the advantage of being more easily carried out at the bedside and in private practise.

Dr. De Marsi, director of the gynecological department of the Polimambulansa, of Bologna, reports an extraordinary case of

supplementary menstruation following total vaginal hysterectomy. The patient, a young woman, was operated on in November, 1896, for chronic metritis and double pyosalpinx, probably gonorrheal. A complete hysterectomy was performed and both ovaries with appendages removed. After the operation the patient presented the phenomenon of an ectopic menstruation from the bladder, which recurred at the regular periods. The microscopic examination of the urine during the menstrual period gave the following constant results: (1) Red and white blood cells in abundance; (2) epithelial cells from the bladder walls; (3) no elements that could be traced to the kidneys, pelvis, or ureters. The chemical and microscopic examination of the urine is absolutely negative during the non-catamenial period. According to De Marsi the case is wholly without parallel.

Capparoni, the Medico Primario of the Roman hospitals, records some brilliant results in the treatment of Pott's disease of the spine with injections of corrosive sublimate. He quotes in all four cases, of which three are cured and one remains under treatment. The first case was one of cervical disease with a marked gibbosity corresponding to the sixth and seventh cervical vertebrae, and some lordosis of the three first dorsal vertebrae. One centigramme of the sublimate was injected daily into the back of the patient, who was discharged after five months' treatment apparently cured. Two years later, however, the disease showed itself again, and the patient was readmitted and subjected to the usual treatment by fixation under another physician. This was continued for two months, but without success, when the injections were recommenced at the suggestion of Capparoni and the patient discharged cured, remaining in excellent health since then (December 30, 1895). The second case, also cervical disease, after 140 injections was discharged cured, showing no spinal deformity, and still enjoys excellent health. The third case had a dorsal deformity, which yielded to 500 injections. The last is still under treatment and is much improved. Dr. Capparoni concludes his observations by stating that in these cases, if we exclude syphilis, we must assume a diagnosis of tuberculosis, and as he is not able to believe that the latter could be arrested by the action of mercury, we must therefore look for the cause of the spondylitis in some other pathogenic agent which is amenable to the therapeutic action of mercury.

A new double salt of mercury has been prepared by Salvatore Arrosto, the chemist, at the suggestion of Miceli, who is using it with excellent results at the Grand Civil Hospital, for the hypodermic cure of syphilis. Miceli is opposed to the usual preparations of mercury; the benzoate, the bichloride, the biniodide, the succinate, the cyanide—all these, he says, are painful to the patient, giving rise to swellings and indurations at the site of puncture. They are so painful, even with the addition of cocaine, as to be, in some cases, an obstacle to the continuation of the treatment. He is also persuaded that the addition of cocaine or morphine to the injection leads to a double decomposition which renders the injection solution of no value. The new salt proposed and used by him is a double hyposulphite of sodium and mercury, which is twice as soluble as the acetate and nearly five times as soluble as the bichloride. One cubic centimeter of the solution, which is the dose, contains one centigramme of the salt, equivalent to about nine milligrammes of metallic mercury. The injections are administered every other day, and in very severe cases daily; they give little or no pain and cause no induration. The hyposulphite of soda reacts favorably on the patients. Many successful cures are scored for the new *Sal Micheli*, as it is called. Stomatitis is rare as a consequence of the injections, if administered on alternate days.

---

*THE TYPHOID EPIDEMIC IN MAIDSTONE, ENGLAND.*

BY DILLON CARBERY, M.D.

---

The personal reminiscences of one who had the privilege of taking a small share in the work during eight weeks of the Maidstone epidemic may not prove uninteresting, although they can lay no claim to be regarded as scientific records.

Viewed as an experience, the episode was most instructive for all concerned, but was not devoid of painful impressions. For the doctors there was a superabundance of hard work, for the authorities anxiety and heavy expenses, and for the people the painful illness and sad family losses. Yet there remains this advantage, that an object-lesson has been afforded such as must surely tend to the advancement of sanitary truths, and eventually to the betterment of the afflicted town itself.

We cannot hope for any final report on the

epidemic for some considerable time; for although it is said to be moribund, the malady is evidently dying hard, and no doubt close upon 1900 cases will have been recorded by the time these lines are in print.

Situated as it is in what is called the Garden of England, the chief town of Kent has many charms and natural graces, not the least of which, until lately, was a low death-rate. About the middle of August, 1897, in hop-picking time, an outbreak of diarrhea, not on a very extensive scale and principally affecting the children, was noticed, and attributed to the unusually dry summer. A few deaths occurred, but as September began the health of the town seemed quite restored. One isolated case of enteric fever had been observed, but this was supposed to have been contracted elsewhere.

About September 10 the medical men found that they were getting very busy, and as time went on they were surprised to see their daily work increasing enormously. As yet no one thought of enteric; some spoke of influenza, others were puzzled. After a few days of general astonishment at the extraordinary numbers of patients claiming their care the truth gradually became manifest. On September 16 thirty-eight cases had been notified, and four days later the epidemicity of the fever was fully recognized in a total of 327 notifications. It was then that the doctors, knowing that there must be a great increase in the number of those affected, telegraphed for help and ordered nurses from London and elsewhere.

The urban council meanwhile was waking up, but was not thoroughly roused until convinced by the medical officer of health that the cause of the evil was a contaminated water-supply. The town was supplied from three sources: from the chalk hills of Boarley and Cossington in the north gravitated two of these supplies; and the third was pumped into a reservoir from Rag-stone Springs, three and a half miles to the southwest. In this—the Farleigh—district two of the springs were at no time above suspicion, and a rapid examination revealed a sorry state of affairs. The Tutsham-in-orchard Spring, used as a watercress bed (!), was the recipient of the drainings of a privy hard by! The Tutsham-in-field Spring had been polluted by hop-pickers.

The latter spring—now known to have been the original source of the poison—was situated in a meadow and rose within a foot or so of the surface, above the layer

of impermeable clay. Through the meadow ran a road unprotected by hedge or fence. Here in August an encampment of hop-pickers was allowed to take up its position, and a very slight knowledge of the hop-picker or his habits makes it clear that pollution of the worst kind would result. Given the fact, as demonstrated later, that enteric fever did exist in this very encampment, and we have as complete a tale of water-borne fever as was ever told, to which it would be superfluous to add that the filter-beds for the water of this area had not been in use for some time.

These facts were of course not known in full during the first days of the epidemic; some indeed denied that the Farleigh water could be at fault, as there were no cases at the Barming Lunatic Asylum in the suburbs of the town, and supplied with the same water. No sooner was the objection made than the outbreak of fever amongst the inmates of the asylum gave it the lie, and the peculiar distribution of the cases, which were confined almost exclusively to the area supplied with the tainted water, made the impeachment of the supply a certainty. In one street, for instance, where on one side Boarley water was used, there were no cases, whereas the opposite side had as many cases as houses; and in a certain terrace the only house to escape the sickness used the water from a private well in the rear, whilst the others drew theirs from the contaminated mains.

And still the cases became more numerous; soon 600 was reached, and the town was in the greatest state of anxiety. About this time the work was heaviest for the doctors, as the district nurses had not yet been imported and the hospitals not organized.

In dealing with so large a number of patients and so serious a malady, much strain was put on the usual practitioners of the town, so they early sought help from outside. In the practise of the Mayor and his son, Dr. C. Pye Oliver, in which I was helping, the method of procedure was simple, and if somewhat laborious, certainly most satisfactory in every other way. Handy portfolios, octavo size, were made for us by the local bookbinders, fitted with strings so as to carry a large number of ordinary clinical charts. These books we took with us on our rounds, and a brief history of every fresh case seen was noted at once on a chart with the usual clinical observations and directions as to food, drugs, and stimulants. If after a few

days' observation the case proved not to be typhoid, the chart was put aside. Thus at any time the number of those under observation, the number notified, as well as a clear record of each particular case, was available. These notes were of further use in enabling us to form an early diagnosis, so as to report more rapidly and with greater certainty to the health office. Of course the work entailed in keeping these accurate memoranda in the midst of so much bustle was great, still it was counterbalanced by the possibility it gave each of us of keeping an intelligent eye on at least eighty synchronous cases. When the nurses came, our private charts were no longer of such primary importance, as charts were issued by the Emergency Committee and kept in the sick-room by the nurse in attendance.

Besides the note-book, each physician carried a bag containing a supply of clinical thermometers and emergency drugs. Where a doubtful case was concerned one of the thermometers was entrusted to the friends with directions to place it under the arm of the patient at a given time. These instructions were carried out quite easily even by the most unintelligent, and when the case was seen again the temperature recorded was a most valuable aid to diagnosis. This simple expedient is of evident value in cases where in ordinary practise enteric is suspected and the doctor is anxious not to alarm his patients or their friends by calling twice or sending a nurse.

Amongst the emergency drugs were tablets of phenacetine (four grains) and caffeine (one grain), which we found an efficient palliative for the initial headache; tablets of opium, of quinine, and hypodermic solutions of caffeine, strychnine, and ether. Lastly, we had a quantity of boracic acid in half-ounce packages; these we left at the houses with instructions to dissolve in one pint of boiling water and to administer from one drachm to one ounce, according to age, every two or three hours. This was an expedient resorted to so as to avoid the terrible stress of work at night in the surgery or office, where at first we were quite swamped by the unusual horde of people who wanted medicine. One of the most arduous tasks we had to perform was this attendance at the surgery; here the clubbers or contract patients assembled in force after 8 P.M., and it was difficult to keep them in order or to attend to their wants. Some indeed were falling ill with typhoid and wished to consult us; others thought they

were and were no less anxious for advice. All wanted medicine. Three hours seldom sufficed to attend to all these people and to send out the drugs ordered during the day. For this reason we used the boracic acid in packages, and it saved a great deal of worry and needless work during the first great rush; as to its curative value I shall have a word to say presently.

Later on, when the nursing staff was complete, we had a series of post-cards printed. On the back were divisions marked for name and address, time of visit, temperature, pulse, respirations, and state of bowels. They were directed to us. Where a case was not seen for twenty-four hours the nurse in charge filled in the form and dropped it into the letter-box. If the case was urgent the card was sent by hand, and from the notes made a very clear judgment could be given as to the nature of the emergency. This precaution saved us a great deal of unnecessary visiting at night, which it was expedient to avoid, as the day work was so arduous that a good night's rest was a *sine qua non*.

Meanwhile the sanitary authorities were no less busy, and orders for the boiling of water and milk were promptly issued. The two suspected springs were cut off, and later the whole of the Farleigh supply. About September 22 a bacteriological inquiry into the condition of the water was entrusted to Dr. Washbourne, of London.

Still the Farleigh mains had not as yet been disinfected, and as there was much popular alarm, fomented no doubt by the warnings of the *British Medical Journal*, the whole system used for the supply of the tainted water was eventually sterilized with chloride of lime. Orders were issued to the inhabitants to open all taps at 11 P.M. on Saturday, October 16, and to close them again at midnight, leaving them closed until the following Monday at 6 A.M. Meanwhile Dr. Sims Woodhead, adviser to the Water Company, was busily employed in throwing one and a half tons of disinfectant into the reservoir, with the result that about 11.30 the disagreeable odor of chloride of lime permeated most of the houses. The germ-bane ran through too prematurely; for the water stored by us in the bath-room for washing purposes became so foul with the advent of the disinfectant that it had to be condemned for use and consigned to the drains.

During the temporary famine that ensued, water was supplied to the town in army carts kindly lent by the military authorities at

Chatham. What subsequently came through the taps on Monday morning was absolutely undrinkable, and the odor of chloride of lime was perceptible everywhere. Unquestionably the germs in the mains must have been routed in those thirty-six hours, for surely they would have preferred death to those pestilential fumes.

Nurses had been gradually drafted into the town by the urban council—some for the district, others for the hospitals. They were lodged at private houses and various institutes as guests or boarders; their numbers increased *pari passu* with the need for their services. We had not, as a friend from Canada suggested, one thousand nurses, but the total figure was not much under four hundred, including private nurses and those sent at the expense of individuals or public bodies. The nurses who were in the service of the corporation and engaged in district work wore a distinctive badge bearing their number. Twelve patients were allotted to each nurse, and to reduce fatigue it was so arranged that the cases of each lay close together—say in one street or on two sides of a block. Morning and evening they visited, taking temperatures, sponging, etc., performing such of the duties of head nurse as were possible under the circumstances. Special cases were seen oftener, and in the houses of these the nurses could usually be found by the doctor when on his rounds.

The friends of the sufferers became by degrees initiated into a sufficient knowledge of nursing and were able to assist the nurses materially; many indeed could interpret the charts, and the patients themselves would sometimes scan their temperature curve with a considerable amount of interest. In one instance a little lad of ten would cry so bitterly if his temperature went up that on one occasion when it reached  $105^{\circ}$  we were obliged to conceal the chart in an adjoining room, where it was kept for the rest of his illness.

In very severe cases where close attention was required, the medical attendant could requisition a night nurse who came on duty at 9 P.M. Of night nurses there was a most efficient staff, mostly recruited from the London Hospital Private Nursing Institution, and to their skilled care many patients undoubtedly owe their lives. The night nurses wore a badge like the others, but with a central disk of carved oak coated with luminous paint.

Volunteers also were not wanting, and

amongst these the Volunteer Medical Staff Corps rendered valuable aid in attending, by night, to such male cases as were unmanageable through delirium.

To the Emergency Committee, a section of the corporation presided over by the medical officer of health, is due the credit of fitting up the emergency hospitals, of which no less than eight, with a total accommodation for over 250 beds, were installed within forty days of the outbreak. It was no light task to undertake, but the ingenuity of the committee soon transformed two or three day schools and as many mission rooms into charmingly appointed little hospitals, whilst a private house with the Salvation Army barracks adjacent was made to yield efficient accommodation for nearly seventy beds.

During the early days of the epidemic it was very necessary to get the severe cases removed, partly for the sake of better nursing and partly as a preventive measure; but when the district nursing was organized it was found more convenient and more beneficial to the patients to treat them in their own homes. The mortality during the first few weeks was high in the hospitals, owing to the fact that only the more severe cases were taken in.

As it was proved during the Worthing epidemic, the best results were obtained where the sick could be kept in their houses under the care of competent nurses.

Early in the epidemic the local soup kitchen, a charitable institution, became overwhelmed by petitions for beef tea and milk from the poorer classes of the afflicted, so to supply the needs of these the guardians of the poor opened a temporary relief station. The distribution of food necessities for the sick was entrusted to the doctors and nurses, who carried order books for the purpose. This poor-law relief, intended only for the necessitous, was asked for and granted to the major part of the working classes, for a family that could not be called necessitous at ordinary times was reduced to poverty if the breadwinner was attacked or a number of the household were simultaneously affected. Milk, eggs, beef and mutton for broth, and all other medical necessities, were supplied freely on the doctor's order. Several of these stations were established, and the demand at each did not slacken until the Central Relief Committee opened their stores in the Corn Exchange. Here were to be distributed the unlimited and varied presents sent to the town by sympathizers all over

England. To enumerate these would be to quote the list of a universal provider. One might mention *inter alia* a ton of arrowroot, between seven and eight tons of wearing apparel, and 30,000 bottles of mineral waters. We were given to understand that there was even a limited supply of coffins and tall hats. To add that such trifles as chartreuse, Benedictine, old cognac and choice brands of champagne were to be had in plenty seems almost superfluous. The distribution of these stores was presided over by a committee and directly effected by officials recruited from the ranks of the schoolmasters whose pædagogia had been emptied of scholars to be filled with typhoid patients.

It was an interesting sight to see the Corn Exchange crowded at all times with the friends of the afflicted seeking this or that requisite ordered by the doctor. Here was a tiny child struggling under her load of sterilized milk and beef broth in tins; there a brother carried a basket of mineral water bottles; some wanted eggs or coffee or brandy, others an ice-bag and a blanketful of ice. Nurses hurried in and out laden with toys for the children, books for the older ones, and garments for all; one carried blankets and sheets, another pillows and a bed-rest.

There could not help but be abuse in this general present giving, and indeed we were only amused to hear that one ambitious woman had succeeded in getting no less than eighteen blankets at different times, said blankets finding their way almost directly to the pawn-shop. This particular form of abuse the Relief Committee were able to prevent by marking all bed necessities and articles of a like nature with a special stamp. Our poor patients wanted for nothing, for water-beds, bedpans, easy chairs, feeding cups, beds, bedding, linen and woollen bedclothing were all forthcoming; in a word, all the paraphernalia of a first-class hospital could be procured on the order of a medical man or member of the committee.

A friend who was passing through the town accompanied me one night on my rounds; he could hardly believe that the first house we visited (where there were four cases) was not a hospital, but only the house of a poor washerwoman. The scrupulous cleanliness and neatness of the rooms, the presence of the bright linen-clad nurse, the snow-white beds with charts above each, the tables for medicine and food, all helped to make the illusion complete.

To mention all that was done by the sanitary authorities would be to give the history of the epidemic in detail. We must not forget the public laundry, however, where all infected linen was sterilized. Special canvas bags were deposited at the houses of the patients, in which the sheets and clothing were placed, to be collected by special vans every day. It is interesting to note that no one in connection with this establishment contracted the fever. This was due, of course, to the fact that the infected articles were not handled at all by the employees, as the canvas bags were tumbled into large iron cradles, which were subsequently lowered by a chain into the boilers.

The cost of all these undertakings was said to be about £1500 a week. The relief fund amounted to about £3000, of which a large portion was collected in the borough of Maidstone.

As to the state of panic in which the inhabitants of the town were supposed to exist, the reports were greatly exaggerated. To a stranger there was but little evidence of that internal disorder suggested in the London papers. To one who knew the town, there were indeed many indications of unwontedness. The groups of nurses hurrying through the streets, the many and varied posters showing forth the efficacy of this or that food, drug, or preventive, or extolling the purity of some new table water, the printed warnings to the public headed "Typhoid Fever," and notices of the Relief Committee were a chronicle of the times for the observant. At the town hall daily could be read the list of fresh notifications and the growing number of deaths.

The streets, too, were unusually empty, owing to the timidity of the agriculturists; and the melancholy spectacle of six or seven funerals streaming in the same direction at the same hour was an ample commentary on the story of the town's disaster. In the shops trade was for a time almost at a standstill, and the constant topic of conversation was the epidemic and the mischief it was working. So keenly was this trade depression felt that the Mayor, himself a medical man, drew up a memorandum stating that visitors to the town need not fear infection in making their usual purchases. This notice, signed by the medical men, was displayed in all the shop windows and distributed through the country. Still visitors were few, and buyers in the market fewer still. Nor would they partake of anything edible. As a prophylactic, how-

ever, they consumed brandy incontinently, much to the delight of the publican, whose town-brewed beer was of course tabooed. The mineral water-makers issued large bills showing that their produce was made with boiled water, but non-local firms profited by the scare. It is on record that five tons of cobnuts, sold in the town, were refused by the consignee as being infective material! Hops in the same way was made unsalable because sent out in packets bearing the fatal word "Maidstone." The acme of the ludicrous was reached when a Liverpool firm in sending a check to a local bookseller requested that no receipt be sent back lest the poison should accompany it!

Still with all the good people of Kent took their troubles very stolidly, and in most cases buckled to and nursed their sick with energy and kindness if not with intelligence. A few cases there were where fear subverted natural affection. A certain man, for instance, sent back his wife to London (where she had been staying a few days) on the very day of her coming home stricken with the fever. On her return to the metropolis she was taken into hospital, where she did well, but her husband, curiously, contracted the fever and died in the first fortnight. It was of course impossible to get servants to help in those houses that were affected. In some childless homes the husband was obliged to give up his work and undertake the unwonted duties of nurse and housekeeper. It was not an uncommon thing for patients to be left unattended for many hours, and in one case I found a poor young woman who had not had any one to give her a drink for over twelve hours. In another house was found a small child alone in one of the up-stairs rooms; her father and mother had both been removed to hospital; she had evidently been forgotten by the neighbors, and was in a very pitiful condition of hunger and fright when discovered. A mother and her two daughters were attended for some days by a child of six; and the nurses reported a case where a man and woman recovering from influenza, with their ailing baby and a boy down with the fever, all shared the same bed. These were sad cases, no doubt; but one could not help feeling that there was grit in humanity when one saw a poor washerwoman sole nurse and servant to her three daughters, her son, and her husband—all abed with the fever.

Even in the midst of all this anxiety and desolation there were times when a humorous

situation or an absurd malapropos lightened the tragedy with a little comedy and laughter.

Amongst what might be called the humors of the epidemic the following, incredible as they may seem, came under my own observation: On one occasion, when at the barber's, a man who occupied the adjacent chair stated that he had seen with his own eyes the typhoid germs in the water, and when asked to explain he assured the gaping audience that by the simple expedient of pouring a few drops of vinegar into a tumbler of water he was enabled to see the microbes crawling up the side of the glass! The opinions of the poorer classes as to the nature of the poison were even more extraordinary. One burly matron assured me that she knew all about typhoid, and with an air of authority expressed her conviction that it was due to a worm that grew in the body! Others, again, had strange tales to tell of the foul condition of the reservoir, and from a solitary eel and a few barrows of mud (which were actually cleared out when the reservoir was drained for inspection) they manufactured several tons of eels and many feet of refuse. Some stated that a dead horse had contaminated the water; others that it was the corpse of a baby, which by some was magnified into that of a woman and by other authorities that of a tramp. The climax of aggravation was attained when an elderly shoemaker confided to me his belief that the body of a nigger had actually found its way into the mains! In spite of these reports, and the repeated warnings and pointed notices of the sanitary authorities, some of the people persisted in drinking the water unboiled. Indeed, in the case of a row of cottages whose supply came direct from the rising main, the occupants actually petitioned the board of the water-works to restore the supply when it had been cut off.

These curious demonstrations of popular prejudice, including the precautions of a stranger who rode one night through the town with his face tightly muffled in a white pocket-handkerchief, though undoubtedly amusing, must pale their lights before the credulity of a family who actually caught in their sink and bottled a fine and large specimen of the bacillus typhosus. On arrival at their door on the eventful morning I was greeted with cries of the wildest excitement mingled with the pitiful wailings of two young patients abed up-stairs. I was alarmed at first, but when assured by two pale-faced girls that they had just caught it and put it

in a bottle, I could not restrain my laughter. They showed me a very large, horny centipede that had been washed out through the tap, and which they were convinced was the very germ itself. My two little patients were horrified into tears by the thought that their vitals were being consumed by an army of scaly reptiles of the same type. It took some time and many playthings to console them.

A very curious superstition was demonstrated to me by an old woman whose daughter had typhoid. When ordered to burn some rags, soiled by the dejecta of the patient, the mother refused to do so, as she had always heard that to burn any of the motions of a human being would inevitably lead to their death from a wasting of the bowels. I have subsequently heard that this belief is prevalent in Italy, more especially in Naples, and is also well known in Ireland. The ultimate disposal of sewage by cremation has, it would seem, some ardent opposers, who no doubt regard it as nothing less than wholesale murder.

As to the special features of the fever, it was decidedly of the text-book variety, presenting the usual varieties and but few abnormalities. Of the so-called abortive cases mentioned by Türgensen, I saw none. There were a few apyrexial attacks in which the temperature never touched  $100^{\circ}$ , and in one of which the curve of fever was only once about normal; in this case there occurred, on one occasion, alarming collapse. A case of the ambulatory type was demonstrated in a woman who confessed to all the symptoms, had a slight elevation of temperature, a most characteristic tongue and a copious rash, but was carrying on her usual occupations in the household and could only with the greatest difficulty be persuaded to accept treatment and physiological rest.

Amongst the most interesting abnormalities may be quoted a case (observed in hospital) where a genuine relapse followed after three weeks of complete convalescence.

On the whole, the prevalent malady was not of a mild type; relapses were common and the course of the pyrexia prolonged. Hemorrhage and delirium were frequent.

One of the most interesting features of the epidemic was the variety of rashes observed, the most puzzling being the scarlatiniform rash, coming on with a sudden rise of temperature, and identical with eruptions due to ptomaine poisoning from ingested foods.

The Tache Bleuâtre was not noticed, much

to the credit of the cleanliness of the Maidstone people. Herpes, though rare, I observed in several cases with or without lung complication. Urticarial, eczematous and sudaminous rashes were plentiful. In one case a hard, papular rash not unlike smallpox showed itself, curiously confined to the palmar surface of the hands. The explanation of the incidence of these rashes we find in a report of the medical officer of health, which discloses the extraordinary fact that there are at least 4000 houses in the borough whose water-closets (save the mark!) are waterless and innocent of flushing appliances! The poisonous effects produced on the inmates of these houses, whose house-drains were little better than elongated cesspools, were only too evident, and no doubt helped materially in increasing the death-rate and number of the affected. The sanitary authorities recognized this fact early, and in every instance the house drains were flushed with the hose and disinfected with crude carbolic acid; but the inmates had become so lowered by the continuous inhalation of noxious gases as to become ready victims to the scourge or to succumb more easily if already affected.

Of enteric fever during the puerperium we had one case. The fever was in its second week when natural labor took place. The child was nursed at the breast by the mother, who attributed her discomfort to the usual phenomena of parturition. The infant showed no symptoms of typhoid, although the lying-in room was shared by a son aged fourteen, whose illness was of the same date as that of his mother. This boy was removed to hospital and the baby put out to nurse, the mother making an excellent recovery.

Amongst the complications thrombosis seemed the most frequent. Pleurisy was also noted, and in one case (out of fifty-six) orchitis.

The treatment adopted was varied, but in the main expectant. Antiseptics had their supporters, and amongst these the boracic acid treatment seemed to afford a certain amount of satisfactory results. It would be inexpedient to rehearse the polemics of this question of antiseptics, but one cannot help thinking that if excessive bacterial action is arrested by their use a point has been gained, adding to the comfort and chances of the patient. However this may be, boracic acid given in the manner I have already spoken of caused no unpleasant symptoms; it was readily taken and retained, and seemed,

speaking roughly, to lessen diarrhea, obviate abdominal distention, and generally to mitigate the course of the fever.

The milk diet was in all cases adhered to, and amongst other preparations humanized milk might be cited as being close upon perfection, more agreeable than peptonized foods, and more easily retained and assimilated. As substitutes for milk, whey with albumen, water and various malt preparations were adopted; but of the exclusive use of the latter I had no experience.

Of alcoholic stimulants a free use was made, in some cases in doses of from fifteen to twenty ounces in twenty-four hours. So general was the recourse to alcohol, indeed, that the wrath of the total abstinence faction was mightily aroused. Some amusing though vituperative letters to the press were the result, in which the abstainers, with the infinite authority of ignorance, condemned the doctors and predicted a mortality of over thirty per cent.

Of other stimulants, strychnine hypodermically gave the most grateful results in heart failure or respiratory weakness.

It was of course impossible to use complete hydrotherapeutic measures, as the full-length bath is not an accessory of the houses of the poor; tepid sponging, however, and cold or ice packs were used as occasion arose.

In comparison with other epidemics that of Maidstone can lay claim to the highest total of cases, with a mortality, if not the lowest, undoubtedly much below the average (December 11: Total cases 1885; mortality 7.5 per cent.). This low death-rate was due no doubt to the energy of the authorities, the skill of the nurses, the generosity of friends all over England who so largely contributed in kind and currency, and, not to be over-modest, to the improved training and more approved methods of the medical profession.

---

*REPORT OF A CASE OF DIPHTHERIA INVOLVING THE LOWER LARYNX, TRACHEA, AND BRONCHI, WITH RECOVERY.*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: Mrs. H., aged eighteen, had a cold since December 1, and on January 7 lost her voice. On January 10 she called in Dr. Truitt, who found the patient suffering with some dyspnea and cough, and a temperature ranging from 102° to 103°. There was no deposit in the pharynx or on the tonsils at this time or subsequently. On the 12th of

January there was coughed up a membrane about three inches long. On the morning of the 13th I was called in consultation; the patient had great dyspnea and coughed up a second piece of membrane about two and a half inches long. Through the courtesy of Dr. McCormick, the city bacteriologist of Norfolk, a culture was made from this and found to be purely diphtheritic. The temperature remained about 102° to 103°, the dyspnea continuing. On the morning of the 13th of January 1000 units of the anti-toxin of Parke, Davis & Co. was administered, stimulating treatment being maintained meanwhile. On the evening of the same day another 1000 units of the same serum was injected. The dyspnea was improved shortly after the first injection; the temperature rose to 104° and remained there until a few hours after the second injection. There was considerable nausea, and on the next morning (the 14th) the membrane shown in the illustration came away with relief of all the symp-

toms, the temperature fell, and the dyspnea was entirely relieved. The patient made an uninterrupted recovery and is now convalescent.

Thanks are due Dr. Gwathmey for mounting the specimen, and Dr. McCormick for making culture.

### ARE THE FLUID PREPARATIONS OF DIGITALIS ACTIVE WHEN MANUFACTURED INTO TABLETS?

BY E. M. HOUGHTON, M.D.,

Lecturer on Experimental Pharmacology, Detroit College of Medicine.

From the above title it may be inferred that the activity of the tablet preparations of digitalis has been questioned, notwithstanding the fact that pharmacists and manufacturing chemists have prepared such tablets for the medical profession for years. Indeed, this paper was called forth by some clinical

experiments which were brought to my attention by the editor of the THERAPEUTIC GAZETTE, tending to show that the tincture of digitalis became inert when exhibited in tablet form, and reported by Dr. Judson Daland to the Philadelphia County Medical Society. I have not been able to find any other reports of experiments on this point, and since the question is one of far-reaching importance, it seemed desirable to make some very careful animal experiments in order to confirm or refute the opinion expressed, and to place the biological results before the medical profession; since by animal experiments we can more exactly study the action of any particular drug upon the various organs than is possible in the human

subject, and the action of the various heart tonics upon the several factors concerned in maintaining the circulation having been very carefully studied in amphibians and mammals.

**Material Employed.**—(1) New tablets prepared from tincture of digitalis, old stock (No. 3); (2) old tablets (two years old), tincture of digitalis prepared from old stock (No. 3); (3) stock two years old, from which tablets Nos. 1 and 2 were prepared; (4) new tablets containing old fluid extract of digitalis; (5) stock two years old, from which tablets No. 4 were prepared; (6) new tablets prepared from a fresh fluid extract of digitalis; (7) new stock from which tablets No. 6 were prepared; (8) blank unmedicated tablets.

Three series of experiments were undertaken in order to decide the question beyond doubt.

The several tablets, and the preparation from which they were manufactured, were each made into a solution, which represented one per cent. of the crude drug. These solutions were numbered one to eight, to correspond to the tablets and other preparations from which they were made. The tablets were brought into solution by first dissolving them as far as possible in a certain amount of ninety-four-per-cent. alcohol, filtering and washing the undissolved portion on the filter with more alcohol, until there remained little possibility of any of the active constituents of the digitalis remaining undissolved. The filtrate and rinsings were then evaporated at about 70° C. to a pilular extract, which was taken up with the requisite amount of as dilute alcohol as would bring the extract into solution. The preparations from which the tablets were made (since they were alcoholic) were evaporated to soft extract, and then taken up with the same strength alcohol as that employed for dissolving the residues left from the tablets.

I. The minimum fatal dose of each of the several fluids was then determined for frogs of the same kind and weight, kept under identical conditions, with the following results:

No. 1.—Min. fatal dose per gm. body weight, .0009-.  
No. 2.—Min. fatal dose per gm. body weight, .0009.  
No. 3.—Min. fatal dose per gm. body weight, .0009+.  
No. 4.—Min. fatal dose per gm. body weight, .0009.  
No. 5.—Min. fatal dose per gm. body weight, .0009.  
No. 6.—Min. fatal dose per gm. body weight, .0006.  
No. 7.—Min. fatal dose per gm. body weight, .0006.  
No. 8.—Several times the amount of this solution, prepared from the blank tablets, as was found necessary to kill with the solutions containing digitalis, failed to produce any ill effect whatever.

In determining the minimum fatal dose, tests were made in each instance upon a number of frogs.

Fluid extract No. 7, from which tablets No. 6 were prepared, was about one month old and from a drug just imported from Germany. It will be noticed that solutions Nos. 6 and 7 were about one and one-half times as strong as the others. However, both the old and the new preparations were much stronger than the average sample.

Very frequently I have found variations of three and four hundred per cent. in the physiologic actions of fluid extracts of digitalis prepared from different samples of crude drug.

While there was a slight variation in the killing power of each of the several solutions, as indicated by the positive and negative signs, no great disparity of strength could be noted between the solutions prepared from the tablets and those prepared from the mother preparations. A careful post-mortem examination of the frogs employed in the experiments was made to determine the condition of the heart. In each instance the organ had ceased beating in the systolic condition; this is practically always the case with the frog's heart when digitalis or other of the heart tonics has been given. It may be gathered also, from the physiological effects of the different solutions, that the active properties of digitalis are not lost more rapidly when the drug is kept in tablets than when it is kept in liquid condition, since tablets No. 1 were equally as strong as No. 2 or preparation No. 3.

II. The action of the several solutions was determined upon the laid-bare frog's heart, the beats being counted at short intervals. Except when the solutions from the blank tablets (No. 8) were employed, the rhythm became slower and slower, and the diastole of the ventricle less and less, while the systole, as shown by the whiteness of the ventricle, became more and more perfect, the heart ceasing to beat in the contracted condition in from ten to fifteen minutes.

No. 1. Normal tracing.  
No. 2. One minute after the application of the digitalis solution.  
No. 3. Seven minutes after the application of the digitalis solution.  
No. 4. Twelve minutes after the application of the digitalis solution.

A number of tracings were recorded on the kymograph from the laid-bare frog's hearts, one of which is reproduced herewith, showing the results of an average experiment.

A comparison of the records 1 to 4 on the tracing shows the following points:

1. The rapidity of the beats became less and less, until the heart finally ceased to beat in twelve minutes.

2. The down strokes in the tracing, which were made as the heart assumed the diastolic condition, became shorter and shorter, until finally they ceased to be made.

3. The systolic pause, as shown by the upper horizontal strokes, became greater and greater until the heart ceased to beat, the systolic standstill being marked by a continuous horizontal line about the same distance from the base line as the top of the up strokes in No. 1.

III. Blood-pressure tracings were made from dogs, under the influence of the several solutions, Nos. 1 to 8. In every instance the results obtained showed the characteristic action of the heart tonics except in the case of solution No. 8, which did not influence blood-pressure or the character of the tracing. It is not possible to show all the tracings taken, but the following will indicate very clearly the results obtained. Each of the tracings was taken from the carotid artery, the solutions being injected into the jugular vein. The tracings are all to be read from right to left.

TRACING NO. 1.

No. 1 shows the action of the solution from blank tablets No. 8: (a) The normal tracing before the solution was injected; (b) five minutes after the injection; c, d and e were each taken at later periods up to one-half hour. Very large quantities of the solution were injected, still no action was manifested

upon the rate or strength of the beats or upon the blood-pressure.

Tracing No. 2 shows the action of the solution from tablets No. 1; while tracing No. 3 is the record of the action of the old preparation No. 3 from which the tablets No. 1 were made. These two tracings show that approximately the same results were produced by the action of the solutions upon the circulatory factors concerned. In each there is a primary slowing of the rhythm without

TRACING NO. 2.

much rise in pressure [from] the action of the drug upon the medullary centers, and the cardiac terminations of the vagus; at the same time the relaxation and contraction of the ventricle is more perfect. Especially is this noticeable in tracing No. 3; five minutes

TRACING NO. 3.

after the introduction of the drug. In a short time, as the drug is pushed, great slowing of the rhythm is produced, and at the same time the blood pressure rises. Both these results show very clearly in No. 3, while in No. 2 there is marked slowing, but less rise in blood-pressure. As the toxic effects become more pronounced the pressure goes still higher and the beats become more rapid, very irregular, and less perfect. Soon the blood-pressure falls and the heart ceases to beat. Post-mortem examination found the heart in the diastolic condition.

The following table gives the numerical results obtained from an analysis of one of the tracings from solution No. 6:

Time.	Beats in 20 seconds.	Low blood-pressure.	High blood-pressure.	Mean blood-pressure.	Remarks.
Min. Sec.		Mm.	Mm.	Mm.	
0	25	60	120	90	Normal.
1	12	52	122	87	Normal.
2	50	24	60	98	1 Cc. solution in the jug. vein
4	7	25	58	130	94
5	50	21	70	144	107
7	..	20	72	150	111
8	30	17	82	160	121
11	..	17	98	178	133
11	30	..	..	..	3 Cc. solution in the jug. vein.
15	..	60	168	194	181
19	..	..	..	..	2 Cc. solution in the jug. vein.
23	40	61	90	130	110
27	..	..	..	..	Dead

Blood-pressure is given in Mm. of mercury.

A point worthy of serious consideration is the variability in the quantity of active constituents in different samples of crude digitalis as shown by physiologic examination. The lack of action manifested by the tablets prepared for Dr. Daland may have been entirely due to an inactive drug having been employed for making into the tincture. The pharmacist may easily be deceived as to the active qualities of the crude drug digitalis, procured on the market for his preparations, as he cannot rely upon the physical appearances as being the correct criterion of strength, and he has no way of making a chemical assay. The only way he can guarantee that his preparations of the heart tonics are physiologically active is by an actual test on animals, or by a clinical experiment. The latter method, of course, should never be employed, as the reaction of animals to the heart tonics is positive.

I believe we are fully justified in drawing the following general conclusion from the above series of experiments: Active fluid preparations of digitalis do not lose in activity by being manufactured into tablets, nor do the tablets become less active by keeping than do the other preparations of digitalis.

#### THE ENURESIS OF CHILDHOOD—THE RATIONALE OF TREATMENT.

By RAYMOND CRAWFURD, M.A., M.D. OXON., M.R.C.P. LOND.,

Assistant Physician to the Royal Free Hospital, and to the Victoria Hospital for Children, Chelsea.

The experience of a large out-patient department of a children's hospital suggests to me that no apology is necessary for the attempt, however trivial, to introduce order

into the therapeutic chaos that hangs about this subject. Medical men seem to have two weapons with which to urge an ineffectual crusade—belladonna and circumcision—and lean to one or the other indifferently, as their tendency is medical or surgical. Each may be an excellent remedy in appropriate cases, but let us pour our libations of belladonna on the altar of Reason, and not on that of Authority, and let us not make a scape-goat of any but an offending foreskin. To this end it is essential to have in mind the exact mechanism of micturition, and the possible derangements that may conduce to enuresis. In infancy enuresis is a normal condition because of the functional immaturity of the centers of inhibition, reflex micturition being not yet resisted by the will. It is as though in infancy the connections of the spinal with the cerebral centers were cut, for will at this period is a negative quantity. The exact condition will be readily seen on reference to Fig. 1, which shows diagrammatically the machinery of micturition in early infancy.

Micturition is, then, practically a simple reflex, as the brain knows nothing of what is taking place in the bladder. At a certain degree of distention the nerve terminals of the bladder convey an impulse to the sensory portion (S) of the spinal center, which communicates it to the detrusor center (D) and the sphincter center (Sph.), so that there is simultaneous contraction of the detrusor urinæ, and relaxation of the sphincter vesicæ, and urine escapes under pressure from the bladder (B). As soon as a few drops of urine have entered the proximal portion of the urethra (C), which is intensely sensitive to its presence, still stronger impulses are conveyed to the sensory spinal center and energetically maintain its activity.

In the very large majority of cases of enuresis we have to deal not with a persistence of this condition, but with a retrograde tendency setting in after full control has been established. In some cases, however, either from improper training by the nurse or from defective educability of the child, it is a mere continuance of the infantile condition, and the requisite treatment is more careful instruction. But in most cases the center of inhibition is developed, and has exercised functional activity, but for some cause or other has lost its supreme control. There is in fact a falling back from the condition shown in Fig. 2 to that of Fig. 1.

FIG. 1.

FIG. 2.

In Fig. 2 the mechanism of full control is shown. The message received at S is communicated to the brain (Br.) and to the detrusor center; the brain in turn relaxes the sphincter, and micturition takes place. The practical question then that arises in cases of enuresis is, how is this retrograde tendency brought about? and on this hinges the whole question of treatment. If the sphincter vesicæ is under complete control of the will, how is it that the balance of power passes over to the side of the detrusor? During sleep the inhibitory influence of the will is very largely in abeyance, so that there is a partial interruption of the connections of the spinal center with the brain center; hence, while diurnal enuresis is comparatively rare, nocturnal enuresis is extremely common. Sleep, then, tends to reopen the reflex arc, and the heavier the sleep the greater the tendency. Again, it is possible that in sleep

the brain center may be disturbed by psychical influences, but I cannot say that I am convinced of such a psychopathic form of enuresis. Such psychic disturbances originating in the brain may conceivably be transmitted as impulses to the spinal centers and induce micturition. The child may dream that he is in a convenient spot to ease himself, and take advantage of it. Certainly some children are intensely sensitive to the uncleanness of the habit, and it is possible that they may thus be subject to some kind of autosuggestion. That such a *reve urinaire* does exist is beyond doubt, but whether it be the cause or the consequence of enuresis is very difficult to decide. Diagrammatically this form of enuresis is shown in Fig. 3. Here the impulse starts from the brain and travels to the sphincter center, relaxing the sphincter, so that a few drops of urine enter the urethra; a message is at once

FIG. 3.

sent to the sensory center, which in turn stimulates the detrusor center, and micturition ensues. The brain need receive no message from the sensory center.

I have never been called upon to treat a case of psychopathic enuresis, and may I never be, if corporal punishment be as suggested the appropriate remedy. I can conceive no means better calculated to rivet the child's thoughts on his urinary apparatus, so as to intensify the mental inclination to a maximum. For such cases suggestion would at least supply a rational procedure. Liébeaut met with some amount of success by this method. He aimed at securing some degree of hypnosis, and then suggested to the child to get up at fixed hours to pass water, gradually prolonging the interval, until control was reestablished.

But over and above the influence of sleep, we have in enuresis to deal with instability or disturbance of some part of the nervous mechanism of micturition. In some cases we find an exalted excitability of the nervous centers so that the response to ordinary excitants is excessive, while in others with a normal nervous system we find irritable or irritated peripheral nerves that stimulate the center too strongly or too often. Thus the nervous system may be hit at the center, in

the cord or in the brain, or at the periphery, in the bladder or its neighborhood. Trousseau regarded enuresis as essentially a neurosis, and it must have struck every one that the sufferers are not of the dull, lethargic order of beings, but are for the most part mentally precocious children, whose nervous mechanism is ever ready to run riot. As might be expected, there is a close relationship of enuresis to the other neuroses of childhood, such as somnambulism, night terrors, and the multiple nervous manifestations of rickets and adenoids. Sometimes this nervous irritability is the remainder of some acute illness, or some prolonged drain on the health and strength of the child. In all these cases anemia is seldom absent, and one can readily understand how such a cause may increase the reflex excitability of the lower centers, so that they respond to minimal stimuli, or may lessen the functional activity of the higher cerebral centers, so as to diminish their inhibitory influence over the spinal centers. The anemia of childhood, though usually referable to bad hygienic conditions and improper feeding, is not infrequently traced to rickets, tuberculosis, rheumatism, and syphilis, and with such an association we may have an important lead in therapeutics. I have been particularly struck with the

frequency of rheumatism in the child or its parents, and its influence seems to me to be due rather to the rapid and intense anemia it produces than to any alteration in the acidity of the urine.

For one or other of these causes the sensory center in the cord is hypersensitive, and stimulates the detrusor center too strongly, while maybe the brain exerts too little energy in maintaining the tone of the vesical sphincter; and if by chance the vesical sphincter be organically feeble, there will be still less opposition to the expulsive force of the detrusor muscle. Thus in front of the nervous background with which we have to deal, there stand two main physical faults: on the one hand there may be excessive irritability of the muscular coat of the bladder, on the other deficient resisting power of the sphincter, or both may be conjoined. The most approved combinations of drugs, the most fashionable alkaloids, can hardly transform a temperament in a few weeks. A spell of running wild in fresh country air, a respite from lessons, a more liberal allowance of sleep, may succeed where medicine has failed to invigorate the nervous system. Where anemia is manifest one may often succeed with some light preparation of iron along with *nux vomica*, with or without adjuvant remedies, as the indications of the individual case suggest. If a rheumatic tendency is established it is well to give salicylates a trial, but not to the exclusion of iron. Now and again I have felt half-ashamed of myself for curing a case by having a crop of adenoids removed, and others unblushingly acknowledge the same success. I am quite clear that tea given to children at the evening meal is sometimes at the root of the disorder, and more than once I have been rewarded by forbidding it; and one cannot be too careful of the state of the digestive system, for like convulsions, enuresis may often be traced to some digestive derangement.

When there is reason to suspect abnormal excitability of the muscular coat of the bladder, belladonna should be given. Belladonna is useless as a specific, invaluable as an adjuvant remedy. It is futile to stake one's expectations on belladonna, when anemia is manifestly the prime cause of the derangement, while a combination of iron and belladonna will in all probability effect a permanent cure. The dose should be pushed to its physiological limits—that is to say, till dryness of the throat, dilatation of the pupil,

or even the specific eruption afford a danger signal. I am in the habit of commencing with ten to fifteen drops of the tincture three times a day for a child of four to five years, and increasing weekly by five drops to each dose till there is some sign either of abatement of the disorder or of physiological reaction. It is of the utmost importance not to abruptly relinquish the drug as soon as the habit is broken, or recurrence will almost certainly lead to disappointment. It is best to maintain for a week or so the full dose, and then gradually diminish the dose over a period of weeks.

Great irritability of the muscle coat is usually evidenced by an imperative call to micturition during the day, as well as by nocturnal enuresis. When the sphincter alone is feeble, there is no imperative desire, but utter inability to check the outflow at intervals even during the day. When weakness of the sphincter of the bladder is superadded to irritability of the muscular coat, no combination is so beneficial as that of belladonna and *nux vomica*; often it acts like magic. Other drugs, such as ergot and *rhus aromatica*, are extolled as substitutes for strychnine, but I have carefully tried both and found them inferior. In severely atonic cases ergot and strychnine may be given in combination. *Rhus aromatica* is most suitably prescribed in the form of the fluid extract with a little mucilage and water; given alone I have found it comparatively ineffectual, but combined with belladonna an excellent combination in some cases in which *nux vomica* has seemed undesirable. The use of the interrupted current has been advocated as a rational measure in these cases of atony of the sphincter, but I can offer no opinion of its usefulness, as I have never employed it myself, nor seen others do so. A disk electrode is placed on the symphysis pubis, attached to the positive pole, and a bougie, insulated except at its extremity, is passed up to the sphincter and attached to the negative pole.

Lastly, the fault may be in the peripheral nerves, that carry too vigorous impulses to the sensory spinal center, so that it acts incontinently in spite of itself. In all cases a careful and minute search should be made for an irritant in the urine, in the bladder, or in its neighborhood, to which it is intimately linked by the nerve plexus of the pudic. Such irritants will of course act at a great mechanical advantage in a neurotic subject, whose central nervous system is disordered.

The greater incidence of the disorder on the male sex seems to me to point to the relatively greater importance of these peripheral irritants, such as one would expect from the length and complexity of the male urethra compared with the female. High acidity of the urine is a well recognized cause, and in specimens that have been brought to me uratic deposits have sometimes been particularly abundant. Then a few drops of liquor potassæ with a little belladonna may be given, till litmus paper shows a neutral reaction of the urine. Nothing could be more prejudicial than cutting down the supply of liquid. Water should be freely given to diminish the concentration of the urine; or milk, one of the best of diuretics.

Other cases seem to depend rather on the increased quantity than on the altered quality of the urine. Thus enuresis is much more common in the winter months than in the summer; sometimes appears to be due to an excessive intake of liquids, and sometimes is a danger signal heralding the presence of diabetes or chronic nephritis. The early hours of the night at which enuresis most often occurs is opposed to its frequent occurrence from overdistention. In these cases it may be well to cut down the amount of liquid taken in the later hours of the day. Such children should be made to pass their water before getting into bed, and again when the parents go to bed, and if possible once again in the course of the night.

In some cases the irritant resides in the bladder itself, maybe in cystitis or calculus, conditions that render its muscle coat unduly sensitive. Such conditions in children are rare, and should be treated on the usual lines. There is also a condition of the bladder which, though more properly an effect than a cause of enuresis, serves to render the habit persistent: this is a contracted state of the bladder, so that it can only hold the smallest amount of urine, and must constantly relieve itself by overflow. In the daytime the child should be encouraged to hold his water as long as possible, so as to exert some distending pressure on the bladder-walls; or it may be necessary to have recourse to forcible distention by the hydrostatic pressure of any antiseptic solution. The treatment is analogous to dilatation of urethral stricture by means of bougies, and as in this latter case should be repeated at intervals so as to prevent recontraction.

Sometimes the external genitals are at fault; one most often finds either a simple

phimosis or preputial adhesions. Neither of these conditions in itself will probably cause enuresis, but only by reason of the balanitis that is set up by the retained secretion. Where preputial adhesions exist, these should be broken down, so that the smegma may be removed. Daily retraction and scrupulous cleanliness, aided by the use of a little lubricating oil, will usually prevent their recurrence. Phimosis may often be successfully dealt with by simple dilatation of the orifice, and in exceptional cases by circumcision. And to stay the surgeon's knife, I should like to put it on record that I have met more than one case of enuresis that had dated definitely from circumcision. This I conceive to be due to exposure of the sensitive glans penis.

Occasionally masturbation and enuresis coexist. Is the one the cause of the other, or is it a casual coincidence? No doubt the habit tends to center attention on the genitals, and may give rise to a psychopathic enuresis. Once or twice I have noticed an extreme hypersensitiveness of the deep urethra on passing a catheter, and the fancy has struck me that possibly repeated masturbation may render the urethra hypersensitive. If this be so, we can easily understand how the entry of a few drops of urine into the deep urethra would stir the spinal center into activity, and cause evacuation of the bladder. The sole justification of this theory is the success of treatment based upon it in a few cases. Local sedative treatment is indicated, such as application of cocaine to the hypersensitive part of the urethra, and daily passage of a catheter, so as to accustom the urethra to resist irritation. If bromides have any place in the treatment of enuresis, these would seem to be suitable cases for their exhibition. For my part I look with suspicion on any drug that deepens the slumber of the higher nervous system.

There is an intimate nerve relation of the bladder with its neighborhood, mainly in the ramifications of the pudic nerve. In this way threadworms, rectal polypi, a loaded bowel, fissures and other local derangements, and in the female vulvo-vaginal catarrh, seem to set some cases in motion. There can be no doubt of the malign influence of constipation, but I cannot say that I have found threadworms with greater frequency in the subjects of enuresis than in other children. There is no need to enlarge upon the appropriate treatment of these several conditions.

*THE USE OF PILOCARPINE IN SOME  
ACUTE INFECTIOUS DISEASES.\**

BY E. W. SAUNDERS, M.D.,  
Professor of Pediatrics, Missouri Medical College;

JOHN ZAHORSKY, M.D.,  
House Physician to the Bethesda Foundling Home;

AND

C. FISCH, M.D.,  
Assistant Demonstrator of Bacteriology, Missouri Medical  
College.

In the study of the physiological action of pilocarpine, it is important to note that urinary solids are excreted with the hyperidrosis induced by the drug. That leucomaines, ptomaines, and possibly toxins, may be similarly excreted has been pointed out by several writers. The intense salivation that follows the administration of a full dose is a far more powerful means of eliminating toxic substances. Moreover, the observations of Sabbatani<sup>1</sup> seem to prove that pilocarpine has a diuretic action. Solomon Solis-Cohen<sup>2</sup> has found that this medication very much increases the diuretic action of sparteine. Clinical observation has convinced us that urinary solids, especially urea, are eliminated in increased quantities under its influence, as was first pointed out by Lauder Brunton. We are compelled to conclude, therefore, that this alkaloid is a potent means of ridding the organism of baneful material. Its value in uremia and dropsy is a long attested clinical fact.

But in enumerating the various sources of elimination, the stomach as an excretory organ should not be forgotten, and the vomiting and diarrhea which frequently ensue after a large dose of pilocarpine are due partly to the irritation produced by the excreted leucomaines and specific toxins.

Great importance, also, must be attached to the powerful cleansing effect on the faucial mucous membrane, which is produced by the outflow of several pints of saliva.

Wallstein,<sup>3</sup> Horbaczewski<sup>4</sup> and Wilkinson<sup>5</sup> have shown that pilocarpine induces a marked leucocytosis. The last writer also describes peculiar changes in the morphological and chemical nature of the oxyphile leucocytes; this, however, is as yet not known to be of any practical importance. But the increased formation of leucocytes suggests that phagocytosis may be promoted, and the production of alexins increased.

Pilocarpine causes enlargement of the spleen, according to Horbaczewski, and this is the more remarkable, since its stimulation of unstriated muscular fiber and the consequent reduction in bulk of other viscera is well known; therefore, this enlargement cannot be attributed to relaxation of the capsule and trabeculae, but must be referred to vascular fulness, and probably to some accumulation of white blood-corpuscles.

In fevers the effect of pilocarpine on temperature is marked, lowering it from one-half to three degrees, this fall ensuing within half an hour after profuse salivation. Reichert<sup>6</sup> holds that this descent in temperature is due more to the lessened production than increased dissipation of heat. No doubt the rapid elimination of the pyrogenic toxins is the chief factor to be taken into account.

We must be careful to distinguish between the primary and the secondary physiological effects of pilocarpine. The former are increased rapidity of the pulse and dilatation of the peripheral capillaries with a resulting diminished blood-pressure. The secondary effects are the diaphoretic and sialagogue influence. We endeavor to obtain these secondary symptoms in all cases. We have administered pilocarpine thousands of times, always with due caution, and have never noticed any depression that might be termed dangerous to life, although the family and attendants of the patient are often seized with panic.

Though the germ theory of disease revolutionized our ideas of pathology, and marked a tremendous advance in medical science, still we have as yet been unable, except in a few instances, to find potent germicides which shall act specifically without toxicity to the organism. The scientist, therefore, has turned to the study of the processes whereby the body overcomes infection, hoping to discover measures whereby cellular resistance may be increased. Already the discovery of antitoxins, alexins, globulicides and agglutinins opens a broad path for the advance of the thinking mind; and the hope is cherished that the production of perfect immunity to all infectious diseases may be the ultimate result of scientific research.

At present our means have not been sufficiently perfected to produce this ideal state. We must therefore resort, in the treatment of most diseases, to means which, while not curing the disease, still modify its course and minimize the danger to the integrity of the tissues and the functions.

\* Read before the Bethesda Pediatric Society of St. Louis, Dec. 10, 1897.

It is still open to grave doubt whether a fully developed infectious disease can be aborted by therapeutic measures other than antitoxins, and therefore in the treatment of any infection it is folly to use powerful antiseptics, which cannot possibly destroy the whole infection, and may be very injurious to the tissue cells; much wiser is it to allow the disease to take its natural course. The symptomatology of most infectious diseases is the physiological action of the specific toxins generated by the actively growing pathogenic bacteria. Under the stimulus of the toxins the antitoxins are gradually formed, and thus a stage is reached where the latter overcome the former. In most diseases the symptom-complex is the result of many poisons, frequently due to a variety of micro-organisms, and even to autointoxication, so that artificial antitoxins would necessarily have to be very complex in constitution to meet all possible exigencies, and their preparation for most diseases oversteps the limits of our present chemical and physiological knowledge.

We are compelled, for a time at least, to allow the cure of the infection by the natural processes, but in all cases the indication is to prevent the accumulation of toxins to such an extent as to act deleteriously on the various organs—even destroying the cellular elements—instead of acting as a stimulant to the formation of antagonistic principles.

Pilocarpine is the most effective agent to stimulate the excretion of noxious substances, without at the same time adding to the general toxemia. In the early stages of most acute infectious diseases a marked insufficiency of renal activity occurs, as shown by analysis of the urine, so that a retention toxemia increases the complexity of the symptoms. In this stage the value of sudorific baths is well known, but more powerful still is the action of this alkaloid in removing poisonous substances, which the paralyzed renal cells refuse to excrete. Pilocarpine is particularly indicated in those infectious diseases in which the fauces are the seat of bacterial growth. The swollen mucous membrane is depleted, pseudo-membranes loosened and washed off, and the bacteria carried away in the flood. The direct cellular resistance to the action of the bacteria is also enhanced by this drug, and it is to be remembered that the increased formation of leucocytes may aid in bacterial destruction by phagocytosis and by alexin production.

Since Brieger has found tetanin in the

saliva, we may well conclude that the time-honored custom of treating acute infectious diseases by inducing salivation was in some respects at least a salutary one, for by the salivary glands, whose secretion is normally albuminous, can the toxalbumins be most readily eliminated. As a matter of fact we know that the urine does not show the presence of toxalbumins, unless the renal function has become damaged to such an extent that the urine is albuminous.

Perhaps an equally important effect of pilocarpine in acute infectious diseases is to be found in its presumed action upon the cells of the liver—for it stimulates more or less every gland cell in the body. The increase of urea points indubitably to an increase of function in the liver cells in one direction, and we may safely believe that its toxilytic function, of which we know with certainty in respect of the alkaloids, is tremendously increased by the administration of pilocarpine. It is credible also that the lymphatic glands may be favorably influenced in their defensive work by the action of this drug.

*Administration.*—The alkaloid should in all cases be used; for the infusion and fluid extract of jaborandi contain besides pilocarpine the alkaloid jaborine, which is antagonistic to the action of the former base, resembling atropine in its action; consequently a very large dose of the crude drug must be given to produce diaphoresis and salivation. It is to the use of the whole drug that many of the cases showing toxic symptoms must be ascribed.

Pilocarpine is prescribed in the form of one of its salts, as the hydrochloride or nitrate. The dose ranges from one-eighth to one-fourth grain. The smaller dose should first be used, and the drug must be pushed until its characteristic effects are produced. It is worse than useless to give doses insufficient to produce the secondary symptoms. Tolerance is soon established, and in certain persons we must gradually increase the dose to the maximum. The physiological action commences within fifteen minutes and lasts from one to three hours. Children and infants need proportionately larger doses; the dose as calculated by Cowling's rule must frequently be doubled. Under one year the weight of the infant is taken for the proportionate dose. In general an infant trebles its weight by the end of the first year; consequently an infant at birth receives one-third and at six months two-thirds of the

dose given to a baby of one year. When speedy action is desired, or the stomach is irritable, the subcutaneous injection is to be preferred; but in most cases it can be given by the mouth. In nearly all infectious diseases the administration should be continued for one or two days only, or until the toxicolytic and eliminative organs are thoroughly capable of performing their function unaided. In erysipelas, however, its continued use for several days is necessary.

We find most physicians hesitate to use pilocarpine, giving as a reason that they fear depression of the heart's action and collapse. Personally, we can say that we have never had occasion to regret its use; however, an insufficient dose of the pure alkaloid may accelerate the pulse and produce flushing of the skin, without any amelioration of the symptoms whatever. Then, again, the drug *jaborandi* may bring about a condition closely simulating atropine poisoning. As a result of excessive depletion—for pilocarpine stimulates more or less every secreting cell in the body—we may have symptoms of collapse; but its action can be instantaneously arrested by a hypodermic injection of atropine, and the system rehabilitated by strychnine.

The contraindications to its use are offered by all diseases producing death by suffocation, and conditions of the heart in which sudden failure might be apprehended—a thing rarely to be feared in childhood in the first stage of an acute infection. Any apprehension of pulmonary edema would form a contraindication. The slightest approach to coma—as in the eclampsia of childhood and of the puerperal state—offers a strong bar to its use. In diphtheria it should not be used after the advent of paralytic symptoms, which may be expected on the sixth day at the earliest. In some patients vomiting is a very distressing effect of the drug. In every case its physiological action is opposed to the digestion and absorption of food, and its administration therefore must be uninterrupted if it has to be prolonged.

*Diphtheria.*—In a previous paper, published in the *Virginia Medical Monthly*, one of us has urged the employment of pilocarpine as an adjuvant to the use of antitoxin in diphtheria. Further experience has only strengthened the position taken then. Complications due to the streptococcus need not be feared when this alkaloid is used. A recent pseudo-membrane is soon washed off by the flow of saliva, and the tonsils and fauces appear smooth and healthy. Local treatment is thus

dispensed with. Moreover, the free salivation prevents the overaccumulation of the diphtheria toxin, while the organism is becoming immunized by the antitoxin administered. The objection has been raised that the antitoxin may be similarly excreted with the toxin, and consequently a less perfect immunization would result; but this theoretical objection is silenced by the laboratory experiments cited in this paper.

An important effect is the excretion by the skin and salivary glands of normal excrementitious substances, thus relieving the renal insufficiency. The sudden advent of convalescence, due to the action of antitoxin, throws a tremendous amount of catabolic products on the emunctories, and the weakened kidneys may not successfully remove them; so here again salivation, diaphoresis and gastro-enteric elimination are salutary. Paralysis and nephritis are very rare sequelæ, when antitoxin is synergized by pilocarpine and administered early in the disease.

In laryngeal diphtheria its use is fraught with danger, unless the case be closely watched. However, our friend Dr. Auler has had phenomenal success in just such cases under the free use of pilocarpine, and Sziklai very strongly advocates its use in croup. In severe cases of diphtheria we may have four intoxications to fight, against only one of which does the antitoxin avail us, to wit: (1) that resulting from the *Klebs-Loeffler bacillus*; (2) that resulting from the pyogenic organism; (3) that resulting from the putrefaction of the pseudo-membrane (perhaps also from necrosis of the underlying tissues); (4) autointoxication.

The objection that might be urged against the use of antitoxin alone is that it acts so slowly, allowing the toxemia unhindered sway for many hours, and then meeting the enemy in one form only. In pilocarpine we find a remedy which admirably supplements the peerless antitoxin. Against a coccus invasion of the throat it is specific, whether in diphtheria, scarlet fever, or influenza.

Of the reality of putrefactive alkaloidal intoxication we are satisfied, not only by the horrible stench, but by the totally changed aspect of the case. The initial high temperature falls on the second or third day to 100° or thereabouts, whilst the pulse becomes more rapid, perhaps slower, but always more feeble. The countenance assumes a peculiar mottled, pallid hue, whilst the patient sinks into a profoundly apathetic condition. It

used to be said that this was due to the pressure of the swollen glands upon the cervical vessels, but of this there was never any proof. Convulsions never occur in these cases, for the paralyzing, stupefying ptomaines hold sway until death. Pilocarpine changes this whole scene within a few hours by eliminating the alkaloids, and perhaps stimulating toxilysis in the liver.

Again, at an earlier stage we are warned of the existence of an overwhelming autointoxication—a retention toxicosis—by the behavior of the kidneys. At the very outset, with a high temperature and active delirium, perhaps convulsions, the urine is almost colorless, and of very low specific gravity. The leucomaines as well as other waste products are, we know, being elaborated in greatly increased amounts, and yet the kidneys refuse to excrete them. Pilocarpine changes this in short order, as shown by the speedy amelioration of the symptoms, and the change in the urine to a dark color and to a higher specific gravity.

Lastly, pilocarpine assists antitoxin in its own proper warfare against the toxalbumin of the diphtheria bacillus, as shown by the fact that we get much more speedy returns from our antitoxin, and by the further fact that we seldom or never are called upon to repeat the injection. Of its signal and marvelous efficacy in this particular the evidence is given by the laboratory experiments we shall cite.

It has been proven that the tetanus toxin is excreted by the salivary glands, and Yarrow has saved animals into which he had injected a fourfold lethal dose of rattlesnake venom, by the use of jaborandi. One of us has made experiments in the laboratory on guinea-pigs, the report of which is added here. This gives unanswerable proof of the value of pilocarpine in diphtheria.

It is well known that in an animal that has received a lethal dose of diphtheria toxin, counteracted by a simultaneous dose of antitoxin, a very slight surplus of toxin proves fatal; in other words, death occurs under these circumstances from a quantity of toxin, which alone would hardly have elicited any reaction whatsoever. As an instance, if 0.1 cubic centimeter of toxin (being the fatal dose) is antagonized in a 250-gramme guinea-pig by 0.1 cubic centimeter of a 1:1000 dilution of antitoxic serum (of 100 units to the cubic centimeter), the addition of 0.02 cubic centimeter of toxin to this dose of 0.1 cubic centimeter is sufficient to kill

the animal within twenty-four to forty-eight hours.

In this experiment 0.02 cubic centimeter of toxin killed the animal, while administered alone the dose would not harm it in any way. This interesting fact was utilized for deciding what effect pilocarpine had in saving the animals from the lethal effect of a surplus of toxin over antitoxin.

Two guinea-pigs, in the first experiment, were injected with 0.12 cubic centimeter of normal toxin, which was mixed with 0.1 cubic centimeter of a 1:1000 dilution of antitoxic serum of 100 units strength (really the serum contained only 95 units to the cubic centimeter). At the same time one of the two received an injection hypodermically of one-thirtieth grain of pilocarpine hydrochlorate. Both animals were kept under absolutely the same conditions. The pilocarpine guinea-pig remained healthy and did not even show infiltration at the site of injection, while the other animal died in thirty-six hours. The post-mortem revealed the typical lesions of diphtheria poisoning.

In another experiment two animals were treated in the same way, only the pilocarpine injection was made twelve hours after the toxin-antitoxin injection. The result was practically the same, except that in this experiment the death of the first animal occurred after forty-eight hours. No infiltration was found in the pilocarpine animal.

There was no time to follow up these investigations any further; the urine ought to be examined, temperatures taken, etc. It seems to us, however, that it is not unreasonable to conclude that the administration of pilocarpine effected the excretion of the surplus toxin in time to save the organism from its assaults—that means to prevent it from acting on the nerve centers.

Since these experiments have been made we have adopted the custom of administering small doses of pilocarpine to goats and cows, which are being immunized against diphtheria, and the mortality of which formerly was quite large. Only the most beneficial results can be reported from this custom, no death having occurred since that time. Furthermore, the increase in antitoxic potency of the serum and milk of these animals is in no way impaired by this practise.

Where in the whole range of experimental medicine (outside of the antitoxins) can the life-saving efficacy of any drug be proved with such mathematical precision?

The literature on the subject of pilocarpine in diphtheria is becoming quite extensive. Originally suggested by Senne,<sup>9</sup> it was strongly advocated by Guttman<sup>10</sup> and Lax.<sup>11</sup> An enthusiastic supporter is Sziklai,<sup>12</sup> who uses it in all inflammations where an exudate is present. Barsky<sup>13</sup> also reports favorably upon it. We find Benesch,<sup>14</sup> Herschfeld,<sup>15</sup> Ketchum,<sup>16</sup> Faludi<sup>17</sup> and others recommending it. Archambault<sup>18</sup> and Laschkewitz<sup>19</sup> several years ago condemned its use, before antitoxin was used.

*Diphtheroidal Angina.*—In all inflammations of the pharynx and fauces accompanied by an exudate pilocarpine is a sovereign remedy. In follicular tonsillitis it is much more effective than benzoate of soda or the salicylates. The depletion, with the thorough washing, suffice to cure the disease inside of two or three days. The fever also rapidly falls and the general symptoms soon ameliorate.

*Scarlatina.*—The experiments in scarlet fever with antistreptococcic serum have not been encouraging, and until a more perfect immunizing agent is found, remedies which meet the general indication of toxemia will necessarily be resorted to. Such a remedy we have in pilocarpine, and we therefore urge its employment in this dreadful exanthema. We believe, with others, that the uncomplicated scarlet fever is exceedingly ephemeral, and the continuance of fever and the production of sequelæ are due to the associated infections by pyogenic micro-organisms.

The dangers of this disease may be classified into those symptoms, complications and sequelæ due to a complex toxemia, and second, those due to faucial and pharyngeal inflammation. In the former class belong the severe nervous and cardiac symptoms, the nephritis, and the inflammation of the serous membranes. By the early and constant elimination of the toxins these dangers may be successfully obviated. The kidney which is so susceptible to the scarlatinal poison refuses at the outset to excrete the toxins, and more than that, is inadequate to rid the body of the normal urinary constituents. And here we wish to protest on theoretical as well as practical grounds against the administration of potassium salts in renal inadequacy, for we know that the potash salts are the most important contributors to uro-toxicity, and their ingestion while stimulating the kidney for a short time must necessarily increase the toxicity of the blood. It is much better to eliminate the toxins as well as some of the

normal urinary constituents by other channels, until the kidneys resume a stronger activity.

Marked as is the effect on the general symptoms, the favorable influence on the faucial inflammation eclipses it. The swollen mucous membrane is very much depleted, diphtheroidal exudate is loosened, and the intense suffering is relieved. Streptococci are washed off from the mucous surfaces and the toxins in the blood are thrown off by the salivary glands. The cervical lymphatic nodes, therefore, receive less poison and their subsequent inflammation and suppuration is prevented. If these nodes are found infected, the depletion of the mucous membranes and removal of the poisons put them in the best way of recovery. We have not encountered any cervical abscesses since we commenced the use of this remedy.

Another very serious sequel; the occurrence of which this treatment prevents, is suppurative otitis. The pharyngeal inflammation extends along the Eustachian tube, causing stenosis, and the accumulation of purulent exudate in the tympanum. But under the influence of pilocarpine the mouth of the tube remains patulous, as the swelling of its lining membrane is diminished, and drainage is not interfered with. We have not had a single case of otitis media suppurativa in the many cases of scarlet fever that we have had under our care in the last three years.

About twenty years ago one of us used pilocarpine in scarlatina without success, owing to timidity in pushing the drug to its physiological effect. It is well to emphasize that the higher the temperature the more pronounced the onset of the infection and the larger the dose that must be given. In these severe cases the pulse becomes much stronger under the influence of a full dose.

We claim, therefore, that pilocarpine meets the requirements of the disease better than any known drug, and in urging its extended use we feel confident that the mortality and sequelæ will be greatly reduced.

*Influenza.*—The bacillus of Pfeifer is universally recognized as the prime factor in the etiology of influenza, but as in scarlet fever, the anatomical lesions depend on secondary infections. The streptococcus is commonly present in the various lesions. Considerable doubt exists as to the site of the primary bacillary growth in all cases, but in our experience the fauces in the vast majority of cases is the infected area. A rhinitis is also a common concomitant lesion.

The angina is especially to be noted, since it presents characteristics which are diagnostic. On inspection we find the posterior and lateral wall of the oro-pharynx, also the pillars of the fauces, tonsils, uvula, and the free border of the soft palate, exhibiting a cardinal red, swollen, succulent and velvety appearance. The inflamed area, on the soft palate especially, shows a distinct line of demarcation from the healthy mucous membrane. The inflammation is bilateral and perfectly symmetrical.

The diagnostic features are the symmetry, the distinct line of demarcation, and in the severer cases the peculiar velvety, succulent appearance.

It is in this variety of grippe that pilocarpine is often efficacious. The headache, rachialgia and pain in the limbs are speedily relieved, the fever is reduced, and the attack frequently aborted; its whole action being similar to that in other anginas.

**Pneumonia.**—The use of pilocarpine in pneumonia has been enthusiastically advocated by Sziklai;<sup>31</sup> in fact, this author urges its use in all inflammations accompanied by any fibrinous exudate. He claims for it, first, a mechanical action, the increased secretion carrying off the exudate; and second, a chemical action, by which is meant the destruction or dissolution of fibrin.

On theoretical grounds it is difficult to understand how pilocarpine can increase the secretion in the air-vesicles, since these are not supplied with glands. The only possibility to be considered is the increase of bronchial secretion and this flowing backwards into the vesicles. This must certainly increase dyspnea and perhaps aggravate the symptoms enormously. But, happily, it is only rarely that the bronchial mucus can be increased to such an extent as to fill the unaffected vesicles.

Resorting to chemical activity to explain the removal of fibrin can be objected to on the grounds that we have no proof of such action in other regions.

We believe on practical grounds that Sziklai has gone too far in his enthusiasm to laud the action of this drug. Yet we must admit that he has found an earnest disciple in Poulet,<sup>32</sup> who reports 104 cases of pneumonia due to influenza treated by pilocarpine with only four deaths. He gives about five-sixths of a grain at a dose, giving one dose each day for two successive days in the early stage of the disease.

Ernest Glass,<sup>33</sup> however, as a result of a

careful analysis of eighteen cases treated by pilocarpine, does not find any benefit, even claiming an extension of the inflammatory process under its use. He believes these results do not justify further trial.

We have tried pilocarpine in a few cases of pneumonia. When the disease is well advanced it certainly is a dangerous remedy. Yet we are convinced that we have aborted a frank pneumonia by a few full doses given at the outset. Probably the same explanation as in other acute infectious diseases pertains here.

The question of pilocarpine in pneumonia is, therefore, still *sub judice*.

**Erysipelas.**—Da Costa's treatment of this disease is becoming more and more the established practise. Anders<sup>34</sup> and Salinger<sup>35</sup> have given their support to it. Barr<sup>36</sup> has reported forty cases treated by pilocarpine with excellent results. J. W. Mitchell<sup>37</sup> and Wheatland<sup>38</sup> also report favorably. We do not hold that the disease can, except in very mild cases, be entirely aborted by the use of this alkaloid; but we do claim that local immunity is more quickly induced, while the inflammation continues to spread at the borders. The swelling and pain are very much diminished, the fever runs much lower, and danger to the nerve centers from toxemia is almost *nil*. We usually continue the administration as long as the disease continues to spread, combining or alternating its use with full doses of camphor, which has a marked effect on the temperature.

Little or no local treatment is necessarily required, but any of the customary applications may be used. Having seen two cases of indelible staining of the skin by ichthyol, we fear to use this application about the face.

**Rubeola.**—The classical treatment of measles is by diaphoretics and diuretics. We have found pilocarpine to be the best remedy to prevent dangerous complications and sequelæ of this affection.

1635 SOUTH GRAND AVE.

### THE TREATMENT OF PULMONARY TUBERCULOSIS.\*

BY C. R. P. FISHER, M.D.,  
Bound Brook, N. J.

The almost utter helplessness of the medical profession, when confronted with a case of pulmonary tuberculosis, has long been a reproach to the practitioners of the healing art. The fact that a case of consumption in the early stages semi-occasionally recovered through removal to a more fitting climate only accentuated that reproach, since it only proved we were powerless to stay the ravages of the disease by any other means. The further fact that autopsies, made in cases of death from other causes, frequently reveal *healed* cavities in the lung is likewise a commentary on our helplessness, for we are ignorant of the means by which such healing was accomplished. In treating a case where the patient, through force of circumstances, could not avail himself of the advantages of climatic treatment, we have been obliged to content ourselves with general supporting treatment, keeping up the general health and nutrition as far as possible, satisfied if by such means we could postpone the inevitable end for a few weeks or months.

The great and increasing prevalence of this disease makes the above state of affairs all the more deplorable. In New York City, where the Health Board requires notification of cases of tuberculosis, there were reported to the Board during the first three months of 1897, *2422 cases* and *1541 deaths*. There is every reason to believe that it is as fre-

quently met with in many other cities, where statistics are not so readily obtainable owing to the fact that notification is not required. That the disease finds its victims in the country as well as in the cities the country practitioner knows only too well—the emaciated, stooping frame, the sallow complexion, the hollow cough, are but too well known to us all. No class is exempt, no walk of life is free from the scourge; we find it alike in the hovel of the poor and the mansion of the rich. "Hope springs eternal in the human breast," and the knowledge that rational medicine offered so little in the way of alleviation and cure has always made the phthisical patient an easy prey to the conscienceless charlatan, whose glaring advertisement of a "Sure cure for Consumption" can be found in the columns of nearly every journal in the land.

Thanks to the labors of the bacteriologists the etiology of the "Great White Death" is no longer unknown to us, and it was but natural that with the discovery of the cause our hopes of finding a cure should be raised to a high pitch. The demonstration of its contagiousness has stimulated work along the line of prophylaxis, so that advanced students of public hygiene are already discussing the possibility of stamping it out; but with the patient—the unfortunate mortal who is already in the clutches of the destroyer—the question is not "Can tuberculosis be *prevented*?" but "Can tuberculosis be *cured*?" Personally, I believe that *in the large majority of cases in the early stages pulmonary tuberculosis can be cured*.

We all remember the *furor* created a few years ago by the announcement that Koch had discovered the long sought for specific for consumption—how eagerly it was taken up by the profession, how reluctantly we were obliged to confess to negative or even harmful results. Yet Koch was upon the right track, although his original tuberculin was not a success, and while the men in active practise were obliged to lay it aside, a few earnest experimenters have gone on with the work, believing that success lay in this direction. Klebs and von Ruck in particular have labored earnestly, and have succeeded in preparing a purified tuberculin which produces results far beyond any other treatment within my knowledge.

Having a tubercular patient some four years ago, who had tried climatic treatment (Colorado) without benefit, if not, indeed, with harmful results, I sent him in the fall of

\*Read before the Somerset County (N. J.) District Medical Society, Jan. 27, 1898.

1895 to Asheville, N. C., placing him under the advice and treatment of Dr. von Ruck, who administered antiphthisin during the following winter. The results were so gratifying that I determined to test the remedy in my practise here, and have done so in six cases, brief histories of which I present herewith. In these histories I have omitted details of other treatment—in all of them general supporting and tonic treatment was carried out. These cases were all treated at home, with either antiphthisin (Klebs) or, what I much prefer, the purified tuberculin (von Ruck), the latter producing far less irritation at the site of injection, thus rendering the treatment less painful to the patient.

CASE I.—Male, aged thirty. This case, while perhaps not coming strictly under the head of cases treated *entirely* at home, possesses such interest as showing what can be done in rather advanced cases (and having been treated at home at intervals since May, 1896) that I introduce his history here. He had a severe attack of gripe in January, 1894, from which recovery was very slow. He made a short trip to Florida in March, and took a severe cold on his return; had very profuse pulmonary hemorrhage in April, followed by tubercular peritonitis. He was ordered to Colorado in September, and returned in June, 1895, worse than when he went. Cough was constant, expectoration free and laden with tubercle bacilli. He was kept at home on general treatment until September, when I sent him to Asheville, and placed him under the care of Dr. von Ruck, by whom he was treated with antiphthisin. Patient returned in May, 1896, very much improved; cough and expectoration nearly gone, chest sounds improved, temperature and weight normal. He has attended to business here since then, with the exception of the month of March, 1897, when he was again sent South as a precautionary measure. A curious circumstance about this case is that three or four times since his return he has had attacks of ordinary intermittent fever; the resulting high temperature seemed each time to light up the old lung trouble, as evidenced by immediate return of cough, expectoration, and râles over the affected area, but each time three or four weeks' treatment with the tuberculin removed all these symptoms, and he goes along nicely until some other slight intercurrent illness disturbs the nutrition and temperature.

CASE II.—Male, aged thirty. Taken with gripe March 12, 1896. History of gradually

failing strength during winter; severe pulmonary hemorrhage April 19; slight dulness and moist râles over part of upper lobe of left lung; copious night sweats. Commenced treatment with tuberculin May 13; at that time temperature ranged from 98.4° to 99.4°; weight 159 pounds. Treatment continued to July 28, when temperature was 97.4° to 98.6°; weight 168½ pounds; no night sweats; no physical signs. He resumed work as a bookkeeper in New York in September, and has not lost a day since. He is now apparently in perfect health, and weighs 170 pounds. This case I consider absolutely cured.

CASE III.—Male, aged about fifty, apparently in good health until August 9, 1896, when he had a severe hemorrhage from the lungs. Sputum mixed with blood until August 20. Lungs examined on September 7. There was slight dulness on percussion over left apex, crepitant râles, prolonged expiration; very little cough; night sweats; temperature 98° in morning, 99.6° in evening. Commenced using antiphthisin on September 16. Patient insisted on going to his business in New York every day, and in all kinds of weather, and absolutely would not take reasonable care of himself. Nevertheless he improved, appetite returned, cough diminished, night sweats lessened and ceased finally about November 1. Treatment continued until December 24, when he objected to its further use. At that time his weight had increased to normal, appetite and color good, and he expressed himself as feeling perfectly well; there was, however, a slight cough still, and roughened respiratory sounds over affected area. He was urged to return later for another course of tuberculin, but he did not do so, and was lost sight of until his death, which occurred suddenly, from hemorrhage, on July 14, 1897.

CASE IV.—Female, aged thirty-five; anemic since childhood; very delicate; slight hacking cough; dulness over right apex; prolonged expiration; loss of flesh; temperature rising to 99.6° in the afternoon. Commenced treatment November 7, 1896; continued improvement till July, 1897. The dulness has disappeared; there is now no cough; temperature and weight normal. This patient I consider cured, though owing to naturally feeble blood-making power she is still under observation.

CASE V.—Male, aged forty. Slight hemorrhage in June, 1896. He came under observation in October, when he had hacking

cough with loss of strength, was steadily losing weight, and had chronic pleurisy over lower lobe of right lung. Commenced tuberculin October 14, 1896. Improved very slowly during the winter. In May the cough had almost entirely disappeared; he had increased in weight to above the normal average; but there were still some friction sounds over affected lung. This man is doing outdoor work every day in all kinds of weather, and is up to his normal strength and weight. While I do not consider him cured, he can be classed as greatly improved.

CASE VI.—Female, aged forty-four, giving a previous history of semi-invalidism since typhoid fever in early womanhood, slight pulmonary hemorrhage in 1885, and chronic ulceration (tubercular?) of neck of bladder for many years. She came under treatment in April, 1897. Had cough, loss of appetite, strength, and weight; prolonged expiration over both apices; evening temperature 99.8°. Treatment continued until July, when both the general condition and the physical signs had so much improved that it was discontinued until October, when it was resumed for two months, as the patient had contracted a severe cold. At this time her cough has almost entirely disappeared, temperature is normal, no physical signs excepting slightly prolonged expiration, weight above normal, appetite and color good. Very much improved, but still under observation.

Of course the use of the tuberculin does not obviate the necessity for using every other means in our power to improve the general condition of the patient. We do not throw aside our sprays, stimulants, concentrated nourishment, etc., in treating a case of diphtheria because we are using antitoxin; so in treating a case of pulmonary tuberculosis, while we use the purified tuberculin, we must also see to it that the patient must be well nourished, that his digestion must be as good as possible, that he must be properly clothed, must take the proper kind and amount of exercise, must avoid taking cold, must have as much fresh air as possible—in short, we must exercise a judicious supervision over his whole mode of living. The key-note is: plenty of proper nutrition to make good blood, and plenty of fresh air to keep that blood properly oxygenated.

I was careful to say in the beginning that I believe that cases *in the early stages* can be cured; no remedy can replace lung tissue which has already been destroyed. It is possible, of course, to benefit advanced cases,

to ameliorate their condition, perhaps to lengthen their lives; but unless the inroads of the disease can be stayed while there is yet sufficient healthy lung tissue to do its work properly, a *cure* is manifestly impossible.

"One swallow does not make a summer," and I am well aware that six cases is a very small number upon which to base any conclusions; but it seems to me that they are valuable both in showing the good results of this treatment and also in showing that these results can be obtained *at home*. Of course climatic treatment is of great benefit where patients can afford to avail themselves of it, but unfortunately many of our cases are so circumstanced as to render it impossible for them to go to Colorado, California, the Adirondacks, etc., nor can they all avail themselves of the advantages of treatment in a sanitarium, though this is undoubtedly to be recommended in suitable cases.

---

#### ESOPHAGOTOMY FOR JACKSTONE IN THE UPPER ESOPHAGUS; DEATH FROM EXHAUSTION.\*

---

BY W. W. KEEN, M.D.,

Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia.

---

Ella D., aged thirteen months, was admitted to the Jefferson Hospital March 30, 1897. At five o'clock on March 27, while on the floor with other children, the child was noticed to have something in her mouth. A moment later she strangled. The mother attempted to clear the throat with her finger, with which she could feel a foreign body, but could not remove it through the mouth. She, therefore, tried to push it down into the stomach. Solid food was given the child in order to facilitate its being swallowed. The child was unable, however, to swallow the solid food and only took the breast milk.

On the 29th of March the child was first brought to the out-patient department, and I saw her. The mother stated that she had swallowed a jackstone. A most careful examination of the throat in the laryngological department did not reveal any such foreign body, nor did external palpation. I did not attempt to withdraw the body or to probe for it, but had a skiagraph taken immediately by Professor Coplin. This showed the jackstone

---

\* Read before the Surgical Section of the College of Physicians, April 9, 1897.

opposite the bodies of the fourth and fifth cervical vertebræ. The next day the child was brought to the hospital and operated upon. The finger could not touch the jackstone, but a pair of curved forceps for foreign bodies in the urethra were found to serve the best purpose. With these the foreign body was caught several times both by Professor Hearn and myself, but it was so firmly embedded that by no possibility could it be extracted. The choice then lay between esophagotomy and gastrotomy. The ingenious snare of Dr. A. C. Wood was tried, but it was impossible to get the whalebone bougie past the jackstone; it seemed entirely to fill the esophagus. The child had a very short neck, but I finally decided to do esophagotomy in view of the high position of the jackstone.

An incision was made in the left side of the neck; the sterno-cleido-mastoid and the vessels were drawn outward and a large arterial branch, presumably one of the thyroids, and a large vein were ligated. These were the only two vessels requiring ligation. The recurrent laryngeal nerve was looked for, but was not seen. As soon as the trachea was discovered and back of it the esophagus, the rounded knob of the jackstone was perceived, both by touch and sight. The tissues of the esophagus around it were already beginning to slough. An incision was made over the foreign body, and it was extracted with considerable difficulty and as slight laceration of the parts as was possible. The wound in the esophagus was closed by three catgut sutures and the external wound was packed with iodoform gauze. At the end of the operation the child was very comfortable and in good condition.

The child was fed every four hours for forty hours by the rectum with milk, and twenty drops of whiskey. On April 1, 1897, at 6 A.M., the child nursed for the first time and took food very well. A slight amount of milk passed into the wound, necessitating the change of the dressing three times in the twenty-four hours. The child did not seem to be particularly hungry, fretful, or restless, and I saw no reason to suppose it would not do well. The wound was doing admirably. At 3 A.M., on April 2, she became very restless and died at 3 P.M., apparently from exhaustion. The highest temperature immediately after the operation was 99.6°, but on April 1 it rose to 101.4°.

The two points worthy of attention in this case are, first, the method of removing the obstruction, and secondly, the cause of death.

Although the child's neck was very short and fat, I decided on esophagotomy on account of the high position of the jackstone. The operative result showed that this was the better plan. I doubt much whether in so young a child the jackstone could have been safely removed by the method adopted by White and Wood in their two cases (*University Medical Magazine*, June and October, 1896). There would have been very severe laceration, I think, of the esophagus above or below the obstruction.

For two days after the operation I fed the child by the rectum, and as she seemed entirely satisfied, was not restless, fretful, or in any other way exhibited signs of hunger, I did not deem it best to feed by an esophageal tube. I regretted afterwards that I had not done so. The child took the breast milk on the sixth day very well, but did not show any special signs of hunger or exhaustion till twelve hours before death.

#### REMOVAL OF A CANCEROUS THYROID.

REVERDIN (*Journal de la Suisse Romande*, Dec. 20, 1897) operated upon a malignant growth of the thyroid because of the dyspnea produced. Adhesions prevented complete removal; there was much bleeding; patient died the next day. Microscopic examination showed that the growth was sarcomatous.

Important diagnostic signs of malignant tumor are dysphagia, radiating pains, edema of the thoracic walls and upper portion of the sternal region. Dysphagia is sometimes caused by retro-tracheal simple goitre, but is rarely absent in malignant neoplasms. The patient did not complain of dysphagia, but autopsy showed the growth extended backward between the trachea and esophagus, limiting mobility of the latter by adhesions. Dyspnea was most pronounced. A colloid growth existed before, but the patient had never noticed the tumor. There was no edema of the external parietes, and thrombosed veins were not encountered during operation. The jugular vein was free; the carotid artery was invaded. Rapid development of paralysis of vocal cords by compression, recurrent radiating pains towards the ear, rapid emaciation and marked interference with respiration were all noted.

When this disease manifests its characteristic symptoms it has acquired such extensive adhesions and has so widely infiltrated that complete removal is exceedingly dangerous to life, and not likely to arrest the disease.

### THE TREATMENT OF NEPHRITIS.

Acute nephritis is by no means so frequently met with as the more chronic inflammatory conditions which produce such disastrous results; yet it is sometimes seen, either as the result of the ingestion of irritant substances or of the presence of severe infections. Some persons have gone so far as to assert that acute nephritis may result from severe exposure. Whatever its causes may be, if it is of a severe character a train of symptoms familiar to experienced clinicians assert themselves. There is a condition of malaise, with anorexia and perhaps nausea and vomiting, while if the condition of the kidneys be grave these symptoms may be followed or supplanted by violent headache, followed by delirium, convulsions, and coma, during which the heart will be found acting laboriously and the pulse will be of high tension. The urine will also be decreased in quantity and the patient may develop rather a typhoid appearance. This condition may last, if not so grave as to pro-

duce death early in its course, for several weeks, and at that time, unless the case has been badly treated or has been unusually severe, recovery takes place, or at least the patient becomes so improved in health as to consider himself well.

The most important thing to do for any patient who is suffering from mild or severe acute inflammation of the kidney is to insist upon absolute rest, the patient remaining in bed not only for the rest, but also in order that the surface of the body may be protected from draughts and colds. A liquid diet, consisting largely of milk, should be insisted upon, and this liquid diet has the additional advantage that it will tend to increase the quantity of urine and so help to wash from the kidneys the effete materials which it is the function of these organs to eliminate. On the other hand, it must not be forgotten that during the course of acute nephritis the kidneys are unable to eliminate as much fluid as they can do in health, and the too free administration of liquids under these circumstances may to some extent aid in increasing the tendency to dropsy. For this reason scantiness of the urine in acute nephritis is not to be considered as a very grave symptom, but if it becomes exceedingly scanty and does not show evidences of being thoroughly laden with excrementitious matter, and if it seems probable that this failure of action on the part of the kidneys is due to congestion, it then becomes the physician's function to relieve that congestion by one or several measures. Dry cups or even wet cups may be applied over the lumbar region, provided that hot compresses applied to this area for an hour or two fail to relieve the congestion. Or in other cases it may be well to cause a flow of blood to the surface of the entire body by placing the patient in a hot wet pack.

As purgatives not only relieve congestion of the abdominal viscera directly, but also seem to indirectly stimulate the kidneys to increased secretion, probably by relieving engorgement, and as calomel is a purgative which is supposed to possess considerable diuretic power, this or some other more rapidly acting drug, such as the sulphate of magnesium, may be given, and this will also aid the body in eliminating poisons through the bowel. Should the arterial tension be great, we are not to forget that in the presence of acute inflammation with high arterial tension, aconite and chloral are valuable drugs which are best given in small doses rather fre-

quently rather than in full doses far apart. Should evidences of cerebral congestion manifest themselves, it may be necessary to resort to hot foot-baths or to actual venesection, the patient being also purged by repeated small doses of Epsom salts. As the end of the period of acute inflammation is approached the anemia, which has probably been gradually increasing, is to be combated by the use of iron and arsenic, though the latter drug is to be administered cautiously lest it irritate the kidney, and solid food may be employed in place of the liquid diet heretofore insisted upon. Oxygen inhalations are also useful to some of these cases. The greatest attention should also be paid to maintaining an active condition of the skin by frequently sponging it with alcohol, or if the patient is strong enough, by frequent washings.

Where the condition of the kidneys is more chronic, or in other words subacute nephritis is present, the patient should be advised, if possible, to resort to a warm and equable climate, to clothe himself most carefully, to avoid wetting the feet, and to limit his diet both as to fluids and solids. The rule in regard to fluids should be that they should not exceed to any great extent the quantity of urine which is passed, although, of course, an amount of liquid over and above that which is passed must necessarily be swallowed to make up for that which is lost through the skin and lung. This is particularly necessary in patients who are suffering from dropsy, more or less well developed. Should the patient not be passing water freely, copious draughts of fluid may be given to him with the object of aiding his kidneys in getting rid of the quantity of urea which should normally be eliminated and which amounts approximately to about 500 grains. If the physician is properly cautious he will from time to time analyze the urine to determine whether the normal quantity of urea is being eliminated, and should it constantly fall below the normal he will know that there is danger of the development of uremia and cerebral symptoms, and arterial tension should be lowered and diuresis encouraged by the use of nitroglycerin. If the dropsy in any case is sufficiently severe to result in large effusions into the various visceral cavities, there is nothing left to do but to recognize the fact that the condition of the kidney is grave; that the prognosis is distinctly unfavorable, and the only measure for relief in addition to those named is the use of tapping

for the purpose of drawing off the liquid. If, as occurs in some cases, where the disease is advanced, arterial tension is depressed rather than raised, digitalis in the form of the infusion, which contains more of the diuretic principle of the digitalis (digitonin) than alcoholic preparations of this drug, should be employed for the triple purpose of stimulating the heart, the arterial system, and increasing urinary flow.

#### *THE VALUE OF BARIUM CHLORIDE IN HEART DISEASE.*

As is well known to pharmacologists, barium chloride in small quantities possesses a physiological action closely allied to that of digitalis so far as its influence upon the heart is concerned. Thus it slows the heart very greatly, steadies its rhythm, and markedly increases the quantity of blood which is thrown out of the ventricle at each contraction. At the same time it increases blood-pressure, as has been proved by the careful studies of Kobert, of Dorpat; and it would seem probable, from the studies of this investigator and others, that it exercises a more powerful systolic influence over the ventricles than does digitalis, the slowing of the pulse being due rather to an excessive systolic action of the drug and to high arterial tension than to any effect which the drug may exercise upon the pneumogastric nerve. The drug is therefore one which apparently should prove useful in a certain proportion of cardiac diseases, which for one reason or another fail to obtain benefit from digitalis, which, of course, is its superior in the majority of cases.

Following these theoretical conclusions, quite a large number of clinicians have employed this drug in the treatment of heart disease with failing compensation, both in adults and children, particularly when the pulse is weak and irregular and is lacking in volume. We have used the drug in a number of cases, some of which we have reported in a communication made some years ago, and in other cases which have not been contributed to medical literature, and we have reached the conclusion that it is of value, but must take a place after both digitalis and strophanthus as a cardiac tonic. The dose for an adult is a teaspoonful of the one-per-cent. solution three times a day to an adult, or one-half this to a child of from six to ten years. These doses are not capable of causing irritation of the gastro-intestinal

tract, and very much larger doses of barium are required before it will act as an irritant poison. There are, therefore, no reasons why it should not be tried in the care of cases which we have mentioned.

#### *THE TREATMENT OF OBSTINATE HEADACHE.*

The intention of this editorial note is not to deal with the treatment of headache by the ordinary remedies such as the coal-tar products, but rather to call attention to the use of another substance which, while it has more limited usefulness, is nevertheless capable of giving marked relief in a certain proportion of cases where acetanilid, phenacetine and similar compounds failed. As long ago as 1889 Lewis and de Schweinitz reported no less than eight cases of violent headache, which had resisted other forms of treatment, which were benefited by the use of the oil of eucalyptus. In the first of these, violent occipital headache with zigzag lines and prodromal hallucinations was entirely unaffected by the administration of full doses of quinine, although there was a marked malarial history. Further than this, correction of errors of refraction did not give relief, but the exhibition of five minims of the oil of eucalyptus five times a day caused a complete cure. In another instance in which there was neither malarial nor rheumatic history, but a severe occipital headache of the congestive type, similar doses of oil of eucalyptus gave relief unless the headache was distinctly dyspeptic. In still another instance a patient suffering from occipital headache of the congestive type, and in whose case cannabis indica and antipyrin were utterly useless, not only was relieved of the individual attacks, but was able to prevent subsequent ones by a few doses of the drug. Perhaps the most interesting case that they report is that of a woman of thirty-three years, with a gouty family history, who had been for some time a great sufferer from hay-fever and who had also suffered from violent headaches of the congestive type, the pain being of a jumping character and spreading over the head, there being associated intense injection of conjunctiva and swelling of the face. In this case, also, the ordinary headache remedies failed, but the oil of eucalyptus given in doses of five minims every four hours gave great relief during the paroxysm, but was most efficient when exhibited during the prodromal period.

Since these studies which we have quoted other investigators have employed the oil of eucalyptus in a considerable number of cases with advantage, and while it is not a remedy which is suited to every case, nor agreeable to take, and while in a certain proportion of cases it may produce disorder of the stomach, it is at least to be remembered when the physician is called upon to treat obstinate forms of head pain not dependent upon morbid growths.

#### *SALOL CALCULI.*

It is not often that insoluble drugs are given for so long a period of time that they accumulate in the alimentary canal and form one mass which may or may not be capable of producing evil effects, and yet every now and again medical literature contains the report of a case in which the prolonged use of some such substance has resulted in the formation of a gastric or intestinal calculus. In this connection it is interesting to note the report made by Mr. Marshall in a recent number of the *British Medical Journal*. Marshall received from Dr. Bradbury an almond-shaped, crystalline mass, possessing a yellowish color, and weighing about one gramme. This mass had been vomited by a young lady who had been taking salol for some months for the relief of intestinal flatulence, and it is interesting to note that the administration of the drug had resulted in marked benefit. After six months had elapsed, during which time she had taken as much as ten grains once or twice a day, she had a very severe attack of colic, with violent vomiting, which nothing would relieve except the administration of morphine. In one of these attacks the calculus already mentioned was vomited, and it was stated by the patient that she had frequently passed similar masses by the bowel. The substance had a salol-like odor and gave the chemical tests of this compound. Further analysis showed that it was practically pure.

Another case by Brossard was reported in the *British Medical Journal* of April 24, 1897, and was that of another female who suffered from gastric dilatation, with paroxysmal gastralgia and frequent bloody vomiting. As the patient refused lavage, the treatment consisted in the administration of large doses of alkalies and a milk diet with salol and calomel in combination. Enormous doses of salol were used, as much as sixty to seventy-

five grains a day. Ten days later the patient (who was usually constipated) suffered from symptoms of intestinal obstruction which lasted for thirty-six hours, notwithstanding the use of purgatives and large enemata and the application of electricity. Finally a movement of the bowels was obtained, and thinking that the pain from which the patient had suffered might be due to a biliary calculus, the stool was carefully washed. About ten calculi were found, the largest of these weighing about thirty grains, and several other small calculi were passed in the two following movements. They all consisted of pure salol.

As Marshall points out, an interesting point in his case is that the calculus occurred in the stomach. In only one other instance is a similar condition reported. Thus Girode, in a case of cholera that had been given salol two days before death, found two masses of salol weighing forty-five grains in the stomach at the post-mortem examination.

Brossard concluded, after consulting a chemist, that the salol had remained unaltered, and thought it was exceedingly improbable that it had been first decomposed and then its constituents reunited. On the other hand, it has been found by experiment that a solution of carbolic acid, which is one of the ingredients of salol, causes powdered salol to agglomerate and after some time to melt, and this occurs very readily at about the temperature of the stomach and intestine during the active processes of digestion. As a result the fluid thus produced is readily caused to solidify when the gastric temperature is lowered by the cessation of digestion or the drinking of cold water, and recrystallization occurs. Marshall believes that salol calculi exist more frequently than is generally thought, and also that some gastrointestinal disease is necessarily present as a predisposing cause to their formation. It is therefore evident that salol is best administered not in plain powder or in pill, but that it should be subdivided by being rubbed up with some innocuous powder, or given in emulsion as originally recommended by Sahli, as by this means the possibility of a calculous formation is reduced to the minimum. Ordinarily we are accustomed to think that the administration of this drug, even should it fail to be dissolved by the intestinal juices, is incapable of producing deleterious results, but Marshall's interesting report indicates that when it accumulates in the intestine or stomach it may produce serious consequences.

#### REDUCTION OF THE DEFORMITY IN POTT'S DISEASE.

In various journals there have recently appeared articles strongly advocating the rapid forcible reduction of the deformity of Pott's disease. The more important of these communications will be found abstracted in the THERAPEUTIC GAZETTE. Some have apparently been founded on extremely limited experience; others upon a most extended and exceedingly successful series of cases. The contribution of Wolff in the *Berliner Klinische Wochenschrift* of February 14 and 21, 1898, reviewing as it does the entire subject, is extremely timely. He points out that Hippocrates states that forcible reduction of the deformity in early cases of Pott's disease was a time-honored procedure. Aurran and David more than a century ago advocated reduction of the deformity by mechanical means, pressure, however, being applied gradually. The teachings of these men were followed with modifications by many others. Forcible reduction was, however, at no time popular. In later times the efforts at reducing deformity have been confined to treatment by Sayre's corset, by suspension, or by various forms of extension.

Three years ago Chipault revived the treatment of forcible reduction under an anesthetic, fixing the spinous processes to each other by means of silver wire, an obviously useless procedure. In 1896 Calot's article appeared. He advised not only stretching the spinal column, but breaking it in two pieces so that the fragments might be put in proper position in regard to each other. The object of his procedure was not merely to lessen deformity, but to cure the spondylitis, and this he stated he had succeeded in doing, claiming for his method that the cure was rapid, safe, and without deformity.

Calot compared the deformity of Pott's disease to that resulting from tubercular inflammation of the hip- or knee-joint. When the disease is of short standing—i.e., has not lasted more than a few months—the irregularity is corrected under narcosis in the following way: Two assistants at the head and two at the legs of the patient make forcible extension and counter-extension, while the surgeon presses with his full force on the projection. As a result the prominent vertebræ sink to the level or even beyond the level of the remaining bones of the spinal column. There is often heard a cracking, showing that the spinal column is broken. The bones

can then be put in proper position. For the purpose of keeping the bones in this position a plaster bandage is applied extending from the head to below the hips. This is applied while the narcosis is still kept up, the parts which it encloses being first enveloped in a thick layer of cotton. It is especially reinforced about the region of the kyphosis. This enables the surgeon to apply the gypsum bandage very firmly. The bandage is allowed to remain in place three or four months and then replaced by another. After the second or third corset the patient may be regarded as convalescing and can wear an apparatus which can be removed. The cure of the deformity requires from five to ten months.

This procedure Calot, to quote his own words, slightly modifies. Instead of wiring the spinal processes together, as does Chi-pault, he resects their extremities and together with them a portion of the often cicatrized skin which lies directly over them. When the deformity is four to eight months old the method is stated to be absolutely and completely satisfactory, and Calot believes that if surgeons generally taught this method every child suffering from Pott's disease would not only be cured, but would grow up without any appreciable deformity. Even when the disease is four to eight years old and bony union has fixed the vertebræ in their false position, complete cure is still possible. In such cases Calot has made a wedge-shaped resection, the base of the wedge being backward and embracing the prominent hump. Posteriorly he removed portions of the three vertebræ, exposing two and a half inches of the spinal cord, which was drawn aside when completing the excision of the wedge. The callus was chiseled through sufficiently to allow the bones to be separated by means of traction and pressure, after which the spinal column was put in proper position.

Among his first thirty-seven cases Calot observed no death. In but one instance was there paralysis of the leg, which proved transitory. Four times ulcers developed under the bandages; these quickly healed. In two cases abscesses developed. Calot exhibited six of his patients before the Academy of Medicine, showing apparently extremely gratifying results.

The claims which Calot makes for this method seem extravagant. Thus, as to the rapidity and thoroughness of cure of tuberculous affections of the spine of similar nature

to those involving other bones, it has long since been shown that cure is by no means accomplished by securing the bones in proper position in regard to each other; indeed, a forcible reduction often seems to stimulate the rapidity of tuberculous involvement.

As a matter of fact, Murray has shown by post-mortem examination that reduction of deformity by no means stops the tuberculous process. Menard has proven by cadaveric experiments that the straightening of the angularity may cause a separation of from one-fifth of an inch to one and a half inches of the anterior portions of the vertebræ, a gap which cannot be filled by bony material. Calot's x-ray pictures, intended to show that this breach is filled in, are, according to Wolff, not satisfactory.

The accidents and difficulties encountered in practising this method of forcible reduction are many.

Brun records a death immediately following the reduction, due, he states, to chloroform. Civel records a death of bronchopneumonia immediately after the procedure. Malherbe treated a boy aged twelve with a gibbus of eight years' standing; the patient became cyanotic, suffered the next day from violent pains in the back and extremities, and died of dyspnea on the eighth day. Section showed there was complete fracture between the ninth and tenth dorsal vertebræ, and a blood-stained exudate in the left pleural cavity. Bilhaut reports three deaths. Joannesco has attempted the method thirteen times and lost three cases. One he attributes to chloroform; in one the cause is not given, although the patient died in forty-eight hours; the third died of bronchopneumonia caused by the reduction. Vulpius noted that a patient could not be restored to consciousness after the anesthetic; the temperature steadily rose, and forty-eight hours later the patient died in coma. Calot himself records two deaths within a few days after the reduction of the deformity. Malherbe observed threatened syncope forty hours after reduction of the deformity, relieved only by removal of the dressing and the restoration of the gibbus. Vincent in three cases found it impossible to reduce the deformity. In five other cases he noticed that even though the deformity was reduced, it recurred under the plaster bandage. The majority of surgeons who have attempted this method hold that its merits and dangers have not yet been settled, and that they must be determined by further trial.

Wolff, however, states without hesitation that this is unnecessary, and that Calot's method should be rejected without qualification, basing his conclusion on Calot's own work. Thus, he states that he has seen the French surgeon reduce deformity in three cases, but in a manner absolutely different from that which he describes. He has utterly abandoned open resection and powerful pressure, advising instead extreme gentleness. Efforts at replacement are continued for only a few seconds and consist in traction upon the spinal column, varying from 40 to 160 pounds, and pressure applied on either side of the gibbus by the thumbs of the assistant exerting a force of from 26 to 80 pounds. The trauma, he states, is no greater than that incident to permanent extension.

This modification is not to be commended, since it accomplishes little and since it is followed by an apparently unnecessarily cumbersome, confining and irksome dressing reaching from the head to the hips. Nevertheless Wolff holds that Calot's contribution and the discussion to which it has given rise have been of extreme service, since they encourage the surgeon in making more vigorous efforts at reducing deformity.

Wolff believes he has, profiting by this method, elaborated a method of treatment which will accomplish much better results than could be hoped for by either the older or the more recent method. He has practised it in twenty-four cases. It consists in the correction of the deformity by suspension and pressure and the immediate application of a plaster bandage. This correction and adjustment of a new plaster is repeated every few days or weeks. The dressing is applied without ether, does not threaten life in a healthy patient, does not break or tear the vertebræ, occasions but slight pain, and does not require the application of a heavy bandage such as the one which Calot advises. Patients are suspended in the ordinary way, the hips being fixed by proper supports. The shoulders are held by an assistant. The assistant presses firmly on either side of the gibbus with the point of the thumb and the middle joint of the forefinger as the extension is applied, and maintains his hand in this position while the plaster is put on. This protects the bony projection formed by the spinous processes from direct pressure. After repeated applications of the plaster very decided improvement is noted. A number of illustrations are given showing the astonishingly good results.

## Reports on Therapeutic Progress

### ON THE TREATMENT OF SOME OF THE MORE COMMON EYE AFFECTIONS.

The *Edinburgh Medical Journal* for November, 1897, contains a continued article by Mr. BERRY with this title, in the course of which he tells us that the treatment of cases of conjunctivitis with marginal ulceration of the cornea should be the same in most respects as that devoted to the cure of keratitis or conjunctivitis alone. Lead lotions must, however, be avoided, as they lead to dense white deposits in the cicatrices, which remain after the ulcers have healed. Where the ulcers are superficial and small, a drop or two of a weak nitrate of silver solution (one grain to one ounce) may be dropped into the eye, after an irrigation with boric acid lotion, once daily for three or four days. This often at once induces healing, even in cases where the ulcers have continued in much the same state previously for a couple of weeks or longer. The ulcers often cause a good deal of pain. To allay this, cocaine may be used (two- to five-per-cent. solution of hydrochlorate), but it is not advisable to apply it very frequently—for instance, every half-hour, as is often done. Immediately before and after each irrigation is sufficient to give relief. It is a good plan, too, to instil a few drops into the eye the last thing at night, as the local anesthesia thus caused often allows the patient to fall asleep, which the pain otherwise prevents. Eserine drops are often recommended for the treatment of catarrhal as well as for other forms of corneal ulcer. The writer has never been able to satisfy himself that they are of any use at all for this purpose, and as they are sometimes actually hurtful, they should not be used. Dark glasses are particularly indicated in all cases of conjunctivitis with marginal corneal ulceration.

Deeper and more rapidly extending marginal ulcers should be brushed once or twice with chlorine water (full strength), or if this is not available, with a two-per-cent. solution of nitrate of silver. The brushing, to be effectual, should be done with some force, the camel's-hair brush being dabbed on to the ulcers several times so as to bring the antiseptic properly in contact with all parts of their surface. By using cocaine this can be done without causing any pain to speak of. Afterwards, dusting with finely powdered iodoform is useful after each irrigation. The

application of iodoform in powder is preferable to its use either in ointment or in gelatin disks, the latter of which dissolve in a few minutes and leave only a comparatively small quantity of the iodoform *in situ*. When deeper marginal corneal ulcerations exist, in the absence of much conjunctival secretion, it is sometimes a good plan, if they do not tend to heal, to cover them with a flap of conjunctiva. This is done by undermining the surrounding conjunctiva with scissors and stitching it forwards.

The main characteristics of the forms of conjunctivitis which have been so far considered are the nature of the secretion from the inflamed mucous surface and the rarity of corneal complications.

In purulent conjunctivitis, on the other hand, serious corneal mischief has always been dreaded. There are, probably, several causes of purulent inflammation of the conjunctiva. Much the most frequent cause, and the one which gives rise to changes which may be taken as the type of those caused in other ways as well, is the gonococcus inoculation. This is met with as gonorrheal ophthalmia and in new-born infants as ophthalmia neonatorum.

Apart from the copious and distinctively purulent secretion of gonorrheal conjunctivitis, which shows itself in two or three days after the first symptoms of irritation have begun, there is rapidly developed a great, often an excessive, inflammatory swelling and tenseness of the eyelids. The ocular conjunctiva and subconjunctival tissue is also swollen, tense, and edematous. This is what is called chemosis. In a few days the tenseness in the lids and ocular conjunctiva, especially the former, subsides, but the pus continues to be formed in great quantity.

It is important, and usually not difficult, to recognize early the specific nature of the conjunctival inflammation. The tense swelling of the lids and chemosis are, in fact, characteristic. The only thing which might mislead one is the appearance presented by severe cases of a muco-purulent type which have been persistently poulticed for a day or two. But even in these there is an absence of the hard, tense swelling presented by most cases of gonococcus or similar infection.

Having regard to the grave consequences to the cornea which a purulent conjunctivitis may entail, the treatment has to be considered not only from the point of view of what is best for the infected eye, but also with regard to prophylaxis in the case of the other

eye. Indeed, the first thing which should always be done whenever there is cause to diagnose a gonorrheal or other purulent conjunctivitis of the one eye, is to actively disinfect the other, and then secure it against the risk of subsequent infection—a risk which, it must be remembered, exists so long as the purulent discharge continues. The disinfecting of the sound eye is of course undertaken on the supposition that it may possibly have been recently inoculated, and may be done in the following way: After dropping a little cocaine solution into the conjunctival sac, the lids are everted, and the mucous surfaces, including as far as possible the folds, painted over with chlorine water. The lid margins are then rubbed freely with little pledgets of absorbent cotton-wool moistened in the same antiseptic. This is followed by a free irrigation of the whole conjunctival sac, with not less than a pint of a two-per-cent. boracic acid solution. A little iodoform or boracic ointment is lastly rubbed along the lid margins and the occlusion bandage applied.

The first indication to be complied with in adjusting an occlusion bandage for this purpose is, of course, to secure the eye from any chance of becoming inoculated by the purulent secretions from the other side; the main risk of such inoculation occurs at night. When the discharge is copious, and the patient lies on the side of the sound eye, some pus may readily find its way across the bridge of the nose, or even be transferred unconsciously by the patient's hands. Such an accident may be prevented by covering the sound eye with a good-sized pad of absorbent cotton-wool, held in place by a properly applied bandage. The following plan may be recommended: Next the eye—*i.e.*, immediately over the closed lids—place a circular piece of lint (two to two and a half inches in diameter) which has been dipped in boracic lotion. Powder a little iodoform over its inner edges, and then cover this with a pad of absorbent cotton-wool, which, to the inner side at all events, projects a little beyond the lint. The pad is then secured first by two pieces of thin tape plaster (one-fourth or one-half inch), placed diagonally across it from forehead to cheek, and further by a dome or thin flannel bandage, eight to nine feet long and two and a half inches wide. One turn of the bandage may first be taken round the head, beginning from the opposite side to that of the eye which is to be covered; the next turn is carried down over the pad below the ear; and the third over the upper part of

the pad, and covering in the ear. This occlusion bandage need not be changed more than once every second day. Such a bandage, while efficiently preventing direct inoculation, has the disadvantage of depriving the patient of the use of his eye. In most cases this is tantamount to keeping him in the dark altogether, as the pain and swelling of the lids make it impossible to see with the affected eye. This privation, added to the trouble and anxiety which his condition cause him, has a very depressing effect upon the patient. It is therefore better, as soon as possible, to adopt some arrangement whereby sufficient protection is provided against inoculation, while at the same time the good eye is not altogether thrown out of use. The simplest and most readily prepared contrivance of this nature is what is known as Buller's shield. This consists of an ordinary watch-glass fixed in an aperture between two pieces of adhesive plaster. The shield may be made and applied in the following manner: After cutting out a rectangular piece of paper five inches long by four inches broad, this is held over the eye in such a position that its inner border just covers the middle ridge of the nose, and its lower border lies horizontally on a level with, or slightly below, the lowest point of the nostril. A circular opening half an inch or so less in diameter than the watch-glass which has been procured for a window is then cut in the paper, the center of which should coincide as nearly as possible with that of the pupil when the eye is directed straight forwards. From this paper pattern two pieces of rubber or other adhesive plaster are cut. Then, holding these two pieces together with their non-adhesive surfaces in contact, and so that edges and apertures exactly coincide, a strip one inch wide is cut off the top and one-half inch wide off either side of one of them. The watch-glass, with its concave side downwards, is laid on the adhesive surface of the smaller piece of plaster, so as to cover in the opening, and the plaster securely fixed round the concave rim of the glass in this position. This piece with its glass is then fitted to the other, so that the two lie with their adhesive surfaces in contact in the same position as they did when the surfaces were reversed. There is thus formed a shield, three margins of the under surface of which can be readily fixed along the forehead, down the side of the cheek, and along the nose. The lower edge is not plastered to the face, so that air gets in behind the shield and prevents dimming the glass.

In applying the shield the watch-glass should be secured in a suitable position in front of the eye, and particular care should be taken that the margin along the nose adheres tightly. An extra strip of plaster may with advantage be fixed over this margin. The advantage of Buller's shield over a regular occlusion bandage is not confined to the relative comfort which the patient obtains; an additional advantage is that it does not as a rule require to be changed, as it admits of a ready inspection of the eye by the surgeon.

In the treatment of the inflamed eye everything must be done which is calculated to prevent the cornea becoming involved. It is well to recognize that the main, if not the only, cause of an accompanying corneal ulceration is an inoculation with the specific discharge in places from which the protecting epithelial surface has been removed. The denuded cornea is certainly easily inoculated. Possibly inoculation may take place even when the epithelial covering remains intact. It certainly does not do so readily, and therefore from a clinical point of view it is well to keep before one the desirability of providing as far as possible for the protection of the epithelium. Careful handling is therefore a most necessary precaution. Removal of the epithelium is too often caused by forcible opening of the swollen lids. Owing to the pain and swelling of the lids, it is no doubt often difficult to get a proper view of the eye without using some force. Perhaps the best plan is to instil a few drops of a solution of cocaine (two to five per cent.) into the eye, and then separate the lids by the finger-tips applied to their margins, taking care not to allow the nails to scrape on the cornea. Indeed, the use of the cocaine should be as much to facilitate gentle handling as to diminish the pain which an examination causes the patient. This is often forgotten, yet it is of great importance. Cocaine should only be used during any manipulations which the treatment renders necessary, not at other times. Elevators or speculum should in general be avoided, and when introduced, and whilst *in situ*, must be kept held away from the cornea, so that the epithelium may not be injured in any movement of the eye. Strong caustic solutions are also liable to injure the corneal epithelium when applied to the conjunctiva. Those most commonly in use are solutions of nitrate of silver and corrosive sublimate. The former should not be used on this account stronger than two

per cent., or ten grains to the ounce, and the latter not more than .002 per cent., or about one grain to the ounce. But it is better to avoid these solutions altogether.

#### THE BECHTEREW TREATMENT IN EPILEPSY.

DE CESARE (*La Riforma Medica*, Aug. 13, 1897) records eight cases of epilepsy treated for a period of six weeks with a mixture of bromide of potassium, codeine, and adonis vernalis, given twice a day (Bechterew treatment). In four cases there was complete suspension of the fits; in three cases the fits were replaced by infrequent attacks of vertigo; and in the last case there were four attacks of vertigo and two convulsions. In each case the attacks were very much reduced in frequency; no bad results were observed. The digestion was not impaired, the pulse was fuller, the temperature normal, diuresis increased, sleep uninterrupted and calm, and the mental condition unchanged. The author believes the results were due to the combination of drugs and not to the bromide alone.—*British Medical Journal*, Oct. 23, 1897.

#### "RHEUMATIC" TETANUS AND THE ANTITOXIN TREATMENT.

STEINER (*Wiener Klinische Wochenschrift*, 1897, No. 36) records two cases of interest from the point of view of etiology and therapeutics respectively. The first occurred in an apparently healthy man of thirty-eight, five days after he had contracted a chill by becoming wet to the skin. There was no obvious breach of surface, but the disease ran a subacute course, and after a month showed no signs of improvement. At the end of this time a large purulent crust was sneezed out of the nose, and from that moment the patient rapidly recovered. The crust was, unfortunately, not preserved, but Steiner considers that infection must have taken place by means of dust somehow introduced into the nose. The case would have formerly been classified as one of "rheumatic" tetanus.

The second patient was a man aged twenty-five, in whom the symptoms followed a cut of the left thumb by a fall. Here the disease was more acute, and on the sixth day the spasm, pain, sleeplessness and profuse sweating had rendered him apparently moribund. Tizzoni's serum was injected to the extent

of 1125 immunity units, followed by 300 units the next day, and 825 the day after; in all 2.5 grains of the dry substance was administered. Half an hour after the first injection the patient expressed himself relieved, and he thenceforward speedily improved; the last spasm occurred the day after the final injection, but a slight rigidity of the left forearm persisted for another fortnight, together with sciatica and more marked rigidity of the adductors of the hip. The curative action of the serum was instanced by the immediate cessation of the excessive sweating, and the return of quiet and sleep, in addition to the marked subjective amelioration. Furthermore, the spasms, which had been excessively violent, ceased at once for eight hours, and those which occurred later were abortive, and for the most part painless. The temperature, which had risen to 101° F., was not at once reduced, showing that its origin must be complex.

It should be mentioned that in both cases all the ordinary drugs were ineffectually employed. From them the author draws the following conclusions: (1) An apparently "rheumatic" tetanus was really due to infection through an unusual channel. (2) This was rapidly and spontaneously cured by the expulsion of the principal source of infection—the crust from the nose. (3) Tetanus antitoxin exerts no noxious influence on the organism. (4) In one case at least it appeared to rapidly cut short the disease. (5) The judicious use of the antitoxin will cure cases that would not have got well spontaneously. Steiner strongly recommends its use in conjunction with local or symptomatic treatment. The seat of infection should first be disinfected, preferably with an iodine compound (iodoform); then large quantities of fluid should be given with the object of washing the toxins out of the organism; next physiological antidotes, such as chloral, morphine and bromide should be administered; and finally, the antitoxin injected. The author believes that the latter is not a chemical antidote, but antagonizes the toxins in complicated and physiological ways.—*British Medical Journal*, Oct. 30, 1897.

#### TREATMENT OF DYSMENORRHEA.

The well known gynecologist, Mr. SKENE KEITH, in the *Medical Press and Circular* of October 27, 1897, in discussing the treatment of dysmenorrhea, tells us that in every case, without exception, general treatment must be

most thoroughly tried first, because many, and certainly all the slighter cases, can be cured or much relieved in this way, and also on account of the very evident objection there is to local interference. It is fortunate that this is one of the conditions which can often be treated without actual local knowledge of the condition of the pelvic organs. The general treatment, and with it the preventive treatment, may now be considered. At the time of puberty enough attention is not given, more especially to the delicate girls, to keep up what is commonly called a good circulation. Many girls get far too little exercise—occasionally far too much and of an unsuitable kind—and far too little care is taken both at home and at school to keep them warm, especially at night. People do not seem to think it matters to let a growing girl go to bed with cold feet, or if they do, imagine that to have a hot-water bottle is coddling. A greater mistake is never made. It is essential that the feet be kept warm during the night whenever there is uterine dysmenorrhea, or indeed whenever there is any pelvic trouble. In some cases it is advisable to have the feet and legs thoroughly rubbed before going to bed.

The preventive treatment consists, then, in keeping the girl warm and in attending to her general health. When a delicate, chilly girl is developing into womanhood, a winter passed in a warm climate may make all the difference whether she is to be a strong or a delicate woman, and at the same time dysmenorrhea, if present, will usually be cured. To most, this form of treatment is not accessible, and we must rely on the avoidance of too many lessons, of too much practising in a draughty schoolroom with probably perfectly cold feet, and on the indulgence in plenty of fresh air, with outdoor exercise—not too violent nor continued for too long at a time—in going early to bed and not being up too early in the morning, in keeping warm day and night, and in the judicious use of the morning bath. Some may be able to bathe in cold water, others will require to have the chill taken off the water, and others again may do well while standing in warm water to have first tepid and then cold water poured over them, and especially down the spine. The best guide to go by is that the person must feel warm by the time she has been dried. As soon as there is the slightest appearance of the "period" the girl must be kept rigidly to bed, and not allowed to get

up until the pain is entirely gone and the flow is either over, or is at least past the worst. A large poultice should be kept over the abdomen as long as there is any pain. For medicine, a brisk saline draught at the commencement, or if possible twelve hours before, and then a mild diaphoretic, with a small dose of bromide of sodium or potassium if the patient be strong, or if weak some aromatic spirits of ammonia are best. Sedatives should be avoided as a rule, and the very favorite remedy—hot gin—should not be prescribed except for the very weak people.

When the dysmenorrhea has lasted for some years, it is more difficult to effect a cure by means such as these, because secondary results have now come into play. In spite of this, they should be tried in all cases where the pain is not very severe for six months, or better, for a year. It cannot be too carefully explained that this general treatment is not meant only to relieve pain at the time, but is intended to effect a permanent cure, otherwise it is difficult or impossible to get the average patient to take the rigid care which is necessary.

With the exception of the use of various drugs there does not seem to be much difference of opinion about the general treatment of such cases, though the necessity for keeping the patient warm is often not insisted on as it ought to be.

When we come to the consideration of the local treatment, we find more or less difference of opinion, and it is not necessary to go over in detail what this one and that one has written on the subject, for they may all be classified. Opinions about local treatment may be divided at present among those who do nothing and will hear of nothing being done; among those who advocate the use of stem pessaries; among those who recommend dilatation, either slight or great, with or without curetting; and among those who advise lateral or posterior division of the cervix. To this number of methods the writer adds two: posterior division of the cervix with stitching; Dudley's operation and the use of the constant current, after Apostoli's method.

(a) Those who will do nothing, and a sub-class, those who very seldom will advise anything, in all probability base their opinion on the very poor results that have come under their notice, either in their own practises or in those of others. This class appears to be a large one.

(b) The stem pessary has had its day in

the treatment of flexions. It is unscientific, and, what is much worse, it can only relieve, seldom cures, and may do harm.

(c) Dilatation requires more consideration; it consists of two kinds—slight and great. The first has its advantages in certain cases. It is suitable in the case of married women, when the flexion is not great. In such circumstances it is used in the hope that by distending the canal impregnation may take place, for if the patient becomes pregnant, the dysmenorrhea is cured. Its purpose is simple, and an anesthetic is not required; it seems to be entirely devoid of danger, and the patient does not require to stay in bed. When impregnation does not occur, the good effect passes off very quickly. This line of treatment is useless when the flexion is very acute; for the unmarried it is also impossible, or, at least, very painful without an anesthetic.

Overdilatation has also its merits. It may be done with tents or the rapid forcible method. The action is not the same; with the tents it is simply a distention of the canal; by the rapid method there is, in addition, more or less tearing of the tissues when the operation is pushed to its fullest extent. Dilatation by means of tents is simply the before mentioned slight dilatation carried a step farther, and under similar circumstances may be admissible.

The advocates of the rapid method claim that it is suitable in all cases, whether the patient be married or not. If it cured or greatly relieved the majority of cases at the first operation, this treatment could have much said in its favor, for it is easy in its performance, and is, so far as the writer has seen, harmless, if the late Professor Spence's saying be remembered, that to pass a bougie through a urethral stricture what was most wanted were patience and sweet oil, though nowadays it would have to be something more than sweet. Many patients are not cured unless, of course, they become pregnant, and the writer has heard a strong advocate of the method say that we must go on dilating until we get a cure. This necessity for repetition is a fatal objection, if by any other method even as great a proportion of cases can be cured by one single operation. With reference to this form of dilatation, there is one thing that must be borne in mind—it is that when the stretching is done it must be done thoroughly. Hegar's dilators, or some similar instruments, are as a rule employed in this country, and they do

very well, though sometimes, when the tissues are very hard, a double bladed dilator does better. Whatever instrument is used, the stretching ought to be carried out while the uterus is fixed by tenaculum in its natural position; not as is taught in some schools, when it is drawn to or outside the vulva.

(d) Simpson's lateral and Sims' posterior division of the cervix must have been performed a very great number of times, often with satisfactory results when the patients were married. The object of both operations is to enlarge the uterine canal; the objection to both is that this result is often only temporary. To give much prospect of the canal remaining open, it is necessary to keep a plug (preferably one of glass) in the canal until the wound or wounds have thoroughly healed by granulation, and then to pass a bougie occasionally. The result of this irritation is that the cervix is apt to become hard, and symptoms may arise of as much importance as those the operation was intended to cure. As compared with dilatation these operations have no advantage; they do not do more good and they may do more harm; they are not safer or more easily performed; and the patient requires to be kept in bed for as long a time.

All these different forms of treatment are wanting in certainty; dilating, division, etc., may result in complete failure; there may be improvement neither in the symptoms nor in the local condition; and it is thus not to be wondered at that many able practitioners are opposed to local treatment. The logical position they have taken up in the past is strongly assailed by Dr. Dudley's modification of Sims' operation of backward division. Indeed, the modification makes such a great difference that it is practically a new operation. What is aimed at may briefly be described as the straightening of the uterine canal, and the healing of the cut surfaces by first intention, so that there will be no hard tissue, or possibility of the old bend returning. The operation was described by Dr. George Keith two years ago for the first time in England. The most essential part of the operation is the accurate stitching together of each half of the wound made when the cervix is divided. Performed with the uterus in its natural position, with the help of a Sims' speculum three-quarters of an inch across, it is not necessary to rupture an ordinary hymen, but it is not an operation to be undertaken by those who either have not the dexterity or have not had sufficient practise

to permit them to do it without drawing the cervix to the outside. Frequently, in bad cases, there is more or less tenderness and swelling in the pelvis, and the result of dragging down a uterus when the pelvis is in such a condition can be easily imagined. By this operation nothing is left to chance, and unless the cuts do not heal the cervix remains permanently in the position and of the shape it is left at the time of the operation. So far as he knows, all the cases he has operated on have been cured or have been improved, not only as regards the monthly pain, but as regards the general health the gain has been well marked. Naturally the early cases have not done so well, on the whole, as the later.

The more the body of the uterus is anteverted, the less perfect is the result likely to be, and special care must be taken in such cases to split as far back as possible. Freedom from pain does not always result immediately, and the greater the anteversion the slower is the complete return to health on account of the old standing congestion of the uterine body. In a few cases the writer has had recourse to electricity to complete the cure. This operation is specially suitable for all unmarried women, and for all married, except those who are afraid of becoming pregnant, as it frequently cures sterility as well as dysmenorrhea. Some there are who will have nothing of the nature of an operation, and for them Apostoli's treatment will give relief.

#### THE TREATMENT OF BRONCHIECTASIS.

ARNOLD CHAPLIN in *Treatment of November 11, 1897*, tells us that in the treatment of bronchiectasis a drug is needed which, while it is strongly antiseptic, must at the same time be pungent and acrid enough to induce violent expulsive efforts. The dilated tubes once being emptied can be kept in that state by repeated recourse to the treatment. A substance which answers these conditions is the common commercial coal-tar creosote. It is antiseptic, acrid, and penetrating, and easily gives off fumes on heating. Three years ago the writer began the use of this substance, and after giving it a thorough trial became convinced that it offered many advantages over other forms of treatment.

In order to obtain success with this method the details must be carefully studied, as in that lies the secret of relief. The mode of application is as follows: A room about seven feet square by seven feet high must be obtained, and this must be rendered tolerably

air-tight. It is well to have the room on the top of the house, or away from it, as there will be less chance of the vapors generated from the creosote causing annoyance to those living in the house. In the center of this room a small stand about one and a half feet high is placed, and on this an ordinary spirit lamp, which admits of being raised or lowered. Over the spirit lamp, on a tripod, an enameled tin dish is placed, and into this is poured about half a pint of the coal-tar creosote. The creosote is heated until the dense, pungent fumes are given off. The patient, clothed in an old dressing-gown, is placed in the room as soon as the lamp is lighted. As soon as the fumes begin to come off, an urgent desire to cough comes on, and soon the cough becomes more or less incessant, and attended with the expulsion of large quantities of phlegm. After the sitting has lasted from half to one hour the patient may leave the room, and wait until the next day before taking another sitting. This should go on steadily from day to day for two months. For the first day or two not much benefit will be noticed, but very soon the expectoration becomes less and the odor less disgusting, and before very long the patient, who before was unbearable, is able to mix with his friends, and, unless he has a fit of coughing, his breath is quite free from smell.

When the writer first tried this treatment he believed that after undergoing two months of it the patient was practically cured, but subsequent investigation has convinced him that he must take a sitting at least three times a week if he will keep his expectoration free from odor. With the cessation of the fetor comes increased appetite and strength. After three years' experience of this treatment the writer has not hesitated in saying that it is superior to all others in his hands, and that although it may not cure, yet it certainly keeps the disease well under control, and opens up to the patient the certainty of enjoying health, strength, and social intercourse, to which before he was a complete stranger. All his cases, with but few exceptions, have been adults. Children do not bear the treatment well, and the benefit to them is not nearly so marked.

A few words may be said about the disadvantages of this method. In the first place the treatment is an unpleasant one, and it requires all the persuasive powers of the physician to keep the patient up to the necessity of going on with the application of the drug;

but after a few sittings patients generally become used to it. Secondly, the fumes of the creosote produce running and smarting of the eyes and nose; but this can be prevented by introducing two plugs of cotton-wool into the nostrils and covering the eyes with a pair of glasses rimmed round with india-rubber. Beyond these there are no drawbacks to the treatment, and it can confidently be recommended as likely to improve the condition of the patient if persevered in for sufficient length of time.

#### THE ANTITOXIN TREATMENT OF DIPHTHERIA.

In the *Western Medical Review* of December 15, 1897, M. D. JONES concludes a paper on this subject by asserting that the value of antitoxin in diphtheria is no longer a question of opinion or theory, but an established fact. The few who oppose it have proved nothing in comparison with the enormous mass of evidence as to its specific value. It may, therefore, be affirmed that the following facts have been demonstrated:

1. That diphtheria antitoxin, where generally employed, has reduced the mortality from diphtheria at least one-half.

2. That it has distinctly favorable effects on the clinical course of the disease, shortening it and lessening its severity.,

3. That the earlier the treatment is commenced the better the results obtained; the mortality, when adequate doses of antitoxin have been given within the first forty-eight hours of the disease, not exceeding five per cent.

4. That antitoxin is a specific against true diphtheria, and less efficacious in mixed infection, but even in these forms of diphtheria it is of decided benefit.

5. That it is not necessary to wait for a confirmatory bacteriological diagnosis, but that in every clinically suspicious case of membranous angina, especially in children, a medium dose of antitoxin should immediately be given, and repeated if required by the further development of the case.

6. That antitoxin is a remedy without serious after-effects in the doses which have ordinarily been employed; that it has no injurious action on the kidneys, the heart, or the nervous system; that it does not entirely prevent albuminuria, heart failure, and post-diphtheritic paralysis, because the effects of the diphtheritic toxin which has already entered the system before the administration

of the remedy, no matter how soon the treatment is begun, are not always completely counteracted by the antitoxin.

7. That the protection conferred by immunizing doses of antitoxin is almost absolute for a short period of time.

8. Antitoxin should begin in early or mild cases in not less than 500-unit doses; for moderately severe or recent laryngeal cases in not less than 1000-unit doses; and in severe faucial or laryngeal cases in not less than 1500-unit doses.

If, in the face of the volume of statistics and testimony in favor of the antitoxin treatment of diphtheria, the writer hears a physician oppose or condemn it, he concludes that he either knows nothing about its use practically, or his experience has been very limited and with an inferior product; or perhaps he has treated the case until all other means have failed—hopeless degeneration of important organs has taken place—when as a last resort he expects antitoxin to accomplish the impossible. Under these circumstances the remedy is not employed scientifically or honestly, and should reflect discredit upon the physician and not the remedy.

In the late administration of antitoxin we merely stop the storm waged against the frail bark of life, as irreparable degeneration has taken place, and it sinks beneath the silent wave of toxemia.

#### SALICYLATE OF METHYL IN ARTICULAR RHEUMATISM.

SIREDEY (*Journal de Médecine*, Aug. 25, 1897), who has made extensive study of the use of salicylate of methyl, gives some particular indications as to its use. He first remarks that salicylate of methyl is not to be confounded with essence of wintergreen, as is not infrequently done. This latter product is much less pure and has not the same active property as the former, besides having a most unpleasant odor and being more irritating to the skin. The method of application is simple. The part having been washed is laid upon a sheet of gutta-percha tissue. The salicylate is now applied directly on to the skin over the affected joint, drop by drop, and the gutta-percha tissue is immediately brought over so as to completely envelop the affected part. A flannel bandage is then applied in the ordinary way. A thin layer of cotton-wool may be used in some cases if the patient does not find it disagreeable or hot. Should it be the hand or foot,

the part can of course be completely enveloped as described. It does not seem absolutely necessary, according to the author, to apply salicylate of methyl directly to the part affected, for, as in the case of the hip where the process of wrapping up to prevent evaporation would be difficult, it seems sufficient to apply it to the thigh immediately below, for the action of the drug is due to its absorption rather than to a merely local effect. The salicylate dressing may be renewed twice in the twenty-four hours if the pains are very severe, and the quantity applied may vary from 50 to 120 drops according to circumstances. It does not seem to produce any unpleasant effect on the skin, merely a slight degree of redness being observed, which is painless and without irritation.

In the case of acute polyarticular rheumatism the author finds the application of salicylate of methyl, as above described, to be well-nigh impossible. Under these circumstances he administers it internally in large doses. But in subacute and chronic cases where fewer joints are affected, and these distally, salicylate of methyl seems to have extremely satisfactory results, being much more marked than those of salicylate of soda. The pains disappeared in two or three hours after the first application, and the author finds that cases which do not respond to this latter are at once relieved by the methyl.

The existence of heart complications seems to be no contraindication; thus the author has applied it in two cases of severe pericarditis, both of which terminated favorably. The same treatment is recommended for gouty arthritis. In the case of infective arthritis the result was not so good, but in large doses a certain degree of benefit was obtained. It would seem that conditions other than rheumatic are controlled by salicylate of methyl. Thus the lightning pains of tabes, tubercular leprosy, Pott's disease, etc., have in the author's hands been much relieved by the application of this drug.—*British Medical Journal*, Nov. 13, 1897.

#### IODIDE OF POTASSIUM IN PHTHISIS.

H. J. VETLESEN (*Norsk Mag. f. Lægevidensk.*, No. 10, October, 1897), following the recommendation of Sticker, has employed iodide of potassium in small doses in the diagnosis of the early stages of pulmonary tuberculosis. In the twenty-seven cases in

which it was used it gave a positive reaction in eight and a negative in nineteen. In these eight cases the administration of the iodide (half an ounce of a 1½-per-cent. solution thrice daily) was followed in from two to three days by the appearance of cough, or by its exaggeration if already present, by the production or increase of expectoration, and by the detection of râles in those parts of the lungs where previously there had been only slight changes in respiration and a little marked lowering of the percussion note. The râle was found to be almost photographically limited to the suspected area, and did not extend beyond it. In only four of these cases was the bacillus of tubercle found in the expectoration, but in the other three the diagnosis of tubercle was facilitated by the existence of other symptoms—swollen glands in the neck, tuberculous disease of the tibia, etc. In the nineteen cases in which the iodide gave no reaction, Vetlesen believes it proven that there was no tuberculosis; and this belief was strengthened by the fact that several of these cases were also tested by the injection of tuberculin, and gave no reaction. The author has kept the patients within his knowledge for two years, and none of them have developed tuberculosis. The conclusion is that iodide of potassium in small doses is an important auxiliary in the diagnosis of the nature and exact position of apical phthisis, especially for practitioners who are not always able to resort to bacteriological examination of the sputum.—*British Medical Journal*, Nov. 13, 1897.

#### SOME POINTS IN THE MANAGEMENT OF ABORTION.

In *Treatment* of November 11, 1897, ARNOLD LEA after some general remarks on this subject says if, in any case, a diagnosis of threatened abortion is made, how should the patient be treated? In the first place absolute rest in bed, and the use of the bedpan for micturition and defecation, should be insisted upon. The administration of a dose of castor oil, or a simple enema, is often required. With regard to treatment by drugs, if hemorrhage is a marked symptom small doses of the fluid extract of ergot, twenty to thirty minims every four hours, should be given, with the object of contracting the uterine vessels, and thus checking further separation of the decidua. This may be combined with small doses of opium.

If pain, the result of uterine contractions,

is the principal symptom, a full dose of tincture of opium—thirty minims or more—should be given. Occasionally this seems to act better if given by enema. It may be repeated every two or three hours if necessary. The fluid extract of *viburnum prunifolium* in thirty-minim doses has also a powerful effect as a uterine sedative, though in some cases it appears to fail completely. It may be given three or four times a day, combined preferably with opium.

This treatment should be continued for several days after the symptoms have apparently subsided. We often, however, meet with cases in which abortion is in progress, or our attempts at checking it have failed. We find the os uteri partially dilated, with the pains strong and recurring regularly. If hemorrhage is moderate in amount no interference is advisable. We must always bear in mind that any manipulation undoubtedly increases to a great extent the risk to the patient, however carefully carried out; and though at times it is necessary, we must always keep clearly before us the serious nature of our proceeding. If hemorrhage is free, and the uterus appears to require stimulation, we may administer ergot in considerable doses—one drachm of the extract every four hours—and we may further introduce into the vagina through a duck-bill speculum a tampon of lint soaked in perchloride (1:3000). This should be firmly packed into the posterior fornix. It often brings about the expulsion of the uterine contents in a few hours, though it should not be used in cases after three and a half to four months.

If these mild measures fail to procure complete expulsion of the uterine contents, we must proceed further. It is probable that sixty to seventy per cent. of abortions terminate naturally without any interference, but in practise we are more often called in to the exceptional cases; still in a large number the use of the above treatment is all that is needed.

It is important to appreciate the condition of the uterine contents at the various periods of pregnancy. Thus, at the end of four to six weeks, the decidua forms the bulk of the uterine contents, which at this time do not entirely fill the uterine cavity. At this period the natural efforts usually suffice to expel the ovum and decidua entirely.

At two months the embryo is much larger, and the decidua vera is thinner and more apt to remain behind after the chorion ruptures and the embryo escapes.

At the end of ten to twelve weeks the placenta is clearly differentiated, and the decidua has, to a great extent, atrophied. Inasmuch as the degenerative changes, which normally occur towards the end of pregnancy, have not taken place, adhesion of the whole or part of the placenta often arises. It is important also to note that occasionally the fetus is expelled, surrounded only by the unruptured amnion, the whole of the chorion and placenta being retained. The writer has observed two cases in which this occurred, and Haultain has recently recorded three instances in his own practise.

If, then, the contents of the uterus are incompletely expelled by the natural efforts within twenty-four hours, several conditions may arise:

Hemorrhage may be profuse. No time should be lost in evacuating the uterus. For this purpose the finger carefully aseptically is the most reliable instrument. If this is insufficient, it may be supplemented by the use of a blunt curette to detach specially adherent fragments. If necessary the cervix must be dilated by Hegar's or Duncan's dilators, and an anesthetic may be required.

There may be no hemorrhage, and within three or four days the contents of the uterus are expelled. To facilitate this ergot may be given. Schwabe has lately insisted on the powerful effect of quinine given in ten-grain doses twice a day. This should always be tried along with aseptic treatment of the vagina and vulva.

Recurrent hemorrhage may be set up. If the above remedies do not cause expulsion of the uterine contents, digital removal, as above described, is indicated.

Hemorrhage may entirely cease for a week or longer; then on some slight exertion, severe flooding occurs. This may continue for weeks at intervals. In these cases a piece of decidua or placenta has become vascular, forming perhaps a small polypus. If neglected this condition may result in grave anemia, though fatal hemorrhage is very rare. The only treatment is exploration of the uterus and removal of the fragment digitally or by the blunt curette.

Decidual endometritis may follow the retention of small fragments of decidua. The uterus remains bulky, and severe hemorrhage occurs at the succeeding menstrual periods. This is best treated by dilatation of the cervix and curetting followed by the application of linimentum iodi, or a solution of carbolic acid in alcohol (twenty-per-cent.).

In very rare cases malignant degeneration of the decidua has followed abortion. This is characterized by irregular hemorrhages, profuse and offensive discharges, with enlargement of the uterus. This is soon followed by fixation of the uterus and metastatic growths in various organs. The only treatment is early extirpation of the uterus *per vaginam*.

In addition to the foregoing, the element of sepsis may at any time be introduced in a case of incomplete abortion. This may be the result of autoinfection from the vagina, especially if some fragments of decidua or clot are hanging out of the cervix, thus forming a suitable medium for organisms to develop; exceptionally it may be due to pre-existing uterine or periuterine inflammation, such as a pyosalpinx or pelvic abscess. Lastly, organisms may be introduced from outside by the finger or instruments. If any signs of infection are manifest, such as offensive lochia, pyrexia, etc., no time must be lost in exploring and emptying the uterus. The sepsis is usually mild in the first place and readily curable by energetic measures. If, however, there is delay the organisms may enter the blood-vessels and lymphatics of the uterus, producing general septicemia, which may terminate fatally, or result in chronic inflammation of the uterus and appendages.

It is important in treating these cases to avoid the use of the sharp curette, as there is great danger of opening up the sinuses and thus facilitating the march of the infection. The finger or a blunt curette should be used, and a strong antiseptic then applied freely to the uterine cavity.

#### HOW TO TREAT SICK-HEADACHE.

Analgesine, says Dr. HIRTZ in the *Journal des Praticiens* of December 11, 1897, is unquestionably a medicament of the first order. Huchard experimented with it as an antipyretic; but it is especially an analgetic, and Germain Sée used it commonly to combat pain. The dose is, so to speak, individual. Some subjects are relieved by a dose of four grains; others require fifteen grains; and sometimes thirty or forty-five grains are necessary to obtain recovery.

Patients should be warned against the abuse of this drug, which has become public property and is frequently taken without the advice of a physician, as it gives rise occasionally to symptoms of veritable poisoning. Analgesine is more easily tolerated when

combined with eight grains of sodium bicarbonate. It may also be administered hypodermically when the condition of nausea dependent upon the headache is too painful and too pronounced to allow of the ingestion of any liquid. It may be given in enemata, from thirty to forty-five grains of analgesine with six drops of laudanum being sufficient for four injections.

Before the employment of analgesine, says the author, caffeine was frequently prescribed, either in potion or in subcutaneous injection, and the following formula by Huchard may be recommended:

R Caffeine,  
Sodium benzoate, of each 660 grains;  
Peppermint water, 8 ounces.

M.

A teaspoonful is to be given every two hours until four teaspoonfuls have been given, each one representing four grains of caffeine. The same dose will be contained in a Pravaz syringe, with the following formula for hypodermic injection:

R Caffeine, 38 grains;  
Sodium benzoate, 44 grains;  
Distilled water, sufficient to make 2½ drachms.

M.

If the sick-headache persists after the administration of analgesine, other drugs may be tried, such as acetanilid. They should not be given except in divided doses, in small capsules containing from three to four grains five or six times a day. Care should be taken not to exceed thirty grains a day.

Phenacetine has the advantage of being almost non-toxic and of provoking much more rarely than analgesine eruptions and symptoms of intolerance. Capsules containing four or five grains may be given four or five times a day.

Exalgine does not give such brilliant results in sick-headache as in the trifacial neuralgias. Four grains may be given at a time, but this dose should not be exceeded, and its action should be carefully watched, as it gives rise to accidents.

Lauder Brunton, says Dr. Hirtz, recommends sodium salicylate combined with potassium bromide. The amount is twenty-three grains of the former and thirty-eight grains of the latter, given in four doses.

Immerwahr, Lewy and Schumann have found in methylene blue a very efficacious remedy for sick-headache, especially the form called angeiospastic. They gave it in doses of a grain and a half four times a day,

combining it with nutmeg as follows, in order to avoid vesical irritation:

- R Methylene blue,  
Pulverized nutmeg, of each 1.5 grains.

M.

This quantity will make one capsule, about four of which may be given a day.

Migraine, which is considered by Schumann one of the best remedies for sick-headache, is a combination of antipyrin and caffeine as follows:

- R Antipyrin, 89.4 per cent;  
Caffeine, 8.2 per cent;  
Citric acid, 0.56 per cent.

M.

Aconitine is sometimes successful when other nervines fail. It is prescribed in globules only, each containing four one-thousandths of a grain, of which two a day may be given.

Guarana contains guaranine, which is identical with caffeine. It is given in a powder in doses of from eight to thirty grains dissolved in water.

Seguin, who was a great advocate of the ocular theory of sick-headache, thought it was frequently due to defects of refraction, and he recommended the employment of mydriatics and the correction of the muscular defects by wearing proper glasses. As an internal remedy, he recommended the extract of cannabis indica, to be given three times a day in pills, each containing a fifth of a grain, which amount may be progressively increased to three grains. Gradle, of Chicago, prefers the tincture of cannabis in doses of from twenty to twenty-five drops twice a day, at an interval of six hours.

Ophthalmic sick-headache during its painful stage is amenable to the same treatment as common sick-headache. Other indications, however, present themselves. This form of sick-headache is associated with nervous affections, such as neurasthenia, hysteria, certain mental troubles, epilepsy, tabes, and general paralysis. The most useful treatment, and the only one really efficacious, given in the interval between the attacks in order to delay their recurrence, is with the bromides. Charcot and Fere, says Dr. Hirtz, laid great stress on the services which this treatment rendered. Potassium bromide, sodium bromide, or a mixture of several bromides, may be prescribed in amounts increased from thirty to ninety grains in twenty-four hours.

Ophthalmoplegic sick-headache sometimes resists all treatment. During its painful stage

antipyrin, phenacetine, exalgine, etc., may be employed. The paralytic stage is frequently rebellious to all therapeutic intervention, and this is explained, says the author, by the anatomical and pathological changes. In one case Gubler found the oculo-motor nerve surrounded by an abundant exudation, with thickening of the pia mater. In a case coming under Weiss's observation the nerve was buried in tuberculous masses; in another the nerve was pressed upon by a fibro-chondromatous tumor. In spite of these facts, which baffle all attempts at cure, either the iodide or the bromide treatment should always be tried. Locally, energetic revulsives may be tried under the form of blisters, the cautery, or even the seton. Not only must the attacks be cured, but, what is more difficult to accomplish, their recurrence must be delayed, in order to render them less frequent, and, if possible, to cause their disappearance. To do this, the various causes which lead to sick-headache should be taken into consideration. The patient should be put upon a strict diet; he should avoid all indigestible food, alcoholic drinks, and liquors, the smallest doses of which bring on an attack of sick-headache in predisposed subjects. The majority of recoveries, according to Dr. Hirtz, are due to extreme sobriety.

Debout recommended the following as a prophylactic measure:

- R Quinine sulphate, 45 grains;  
Pulverized digitalis flowers, 23 grains;  
Syrup, a sufficient quantity.

M.

This quantity will make thirty pills. The dose is a pill every night for a period of several months.

In arthritic, rheumatic and gouty persons, the following treatment is recommended by the author: The patient is put upon a strict diet; nitrogenous or indigestible food, especially vegetable, is not allowed at night, and water or a drink like weak tea may be taken. In the morning, before eating, Carlsbad or Tarasp water, heated to about 104° F., may be taken, or else Vichy water. Every night, before supper, a pill containing the following mixture may be taken:

- R Quinine valerianate, 15 grains;  
Extract of colchicum, from 3 to 7 grains;  
Extract of digitalis, 3 grains;  
Extract of aconite, 1½ grains.

M.

This quantity makes ten pills.

Neurasthenic sick-headache is best benefited by living in the country, moderate

muscular exercise, and a quiet life free from professional occupations. It may be overcome by the employment of the phosphates or the glycerophosphates, the use of which may be alternated with arsenic under the form of Fowler's or Pearson's solution, in amounts of from six to twelve drops a day; or strychnine arsenate may be used in globules containing fifteen one-thousandths of a grain, of which from two to three a day may be given.

Hydrotherapy, static electricity and psychotherapy are, says Dr. Hirtz, ordinarily valuable adjuvants.

#### *THERAPEUTIC PROGRESS IN 1897.*

Under this heading the London *Lancet* of December 25, 1897, points out editorially that although the publications connected with the treatment of disease have, as usual, been very numerous during the past year, interest continues to center round the different applications of various forms of serum treatment. The record of cases of diphtheria treated with antitoxic serum has fallen, or at least the number of publications is less than in the previous year, but this appears to be due to the more general acceptance of antitoxin. The cases which are published include a series of triumphs and, as usual when the majority are agreed upon any given point, there is less room for debate and less need for the record of experiences. More recently greater attention appears to have been directed to the use of tetanus antitoxin, and in spite of the value of experimental work it must be admitted that the clinical results have been frequently disappointing. Side by side with these investigations much valuable work has been done in connection with many of the older remedies.

The list of new drugs to be enumerated is this year comparatively small, and even in this list, with one or two exceptions, the novelties do not seem to be of any great importance. Questions connected with therapeutics have been freely discussed, and the best indication of the tendency of the view of modern physicians was perhaps afforded by the debate on the treatment of insomnia at Montreal. We have in these pages long protested against the continuous administration of hypnotics, and from time to time have sounded a warning note of the dangers connected with many of the newer hypnotics. Hence, we are entirely in accord with the discussion at Montreal, since it

showed that most of the speakers were far from being content with the routine employment of any particular drug. The discussion in many ways served to indicate the limits of utility of different hypnotics, such as sulphonal, paraldehyde, urethane, and the like. Some of the speakers mentioned comparatively new remedies, such as pellotin, trional, and chloralamide, but the whole tendency of the discussion indicated that the causes of insomnia, rather than new remedies, should be sought for.

Perhaps the greatest amount of literature in connection with new remedies deals with the search for a satisfactory local anesthetic. It is not so many years since cocaine was introduced with such extremely laudatory notices that it was perhaps somewhat too indiscriminately used and soon claimed a fairly large percentage of undesirable effects. Most of these effects were absent, or at least were thought to be absent, with eucaïne, a remedy which was fairly largely employed in 1895 and 1896. From the first some patients complained bitterly of the smarting or burning pain which resulted from the local application of eucaïne, and, although the subsequent anesthesia was sufficiently satisfactory, it was felt that it had been rather dearly purchased. It is perhaps yet too early to determine the future position of eucaïne in medicine, but nearly all the published accounts during the year have shown dissatisfaction with the drug, even although its anesthetic powers are fully recognized. On the other hand, in its favor it may be stated that it appears to produce toxic symptoms comparatively rarely and that the toxic dose is greater than that of cocaine. Another local anesthetic—which in composition is said to be closely allied to phenacetine—is holocaine. This also causes some transient sense of burning when applied to the conjunctiva, but it has been claimed for this drug that it has no effect on the pupil, on accommodation, or on the blood-vessels. Inasmuch as this drug has only very recently been employed, the published accounts so far are purely laudatory. Orthoform and anesin are two other local anesthetics of recent introduction, of which, however, very little is yet known. Some interesting experiments have been made with the view of determining the activity and purity of cannabinol, which seems to produce symptoms practically identical with those of Indian hemp; while further experiments have been made with mescal, which obviously possesses a some-

what dangerous power of producing subjective visionary sensations. The accounts of the effects produced by this drug written by Dr. Weir Mitchell and Mr. Havelock Ellis will probably be read as interesting contributions to medical literature, even though they do not pretend to have any therapeutic application.

The position of quinine in medicine appears to be established on such a firm basis that it is rather a shock to find recommendations of substitutes for it. The claims of the substitutes are invariably that they produce less giddiness and tinnitus, while they are credited with similar powers of lowering the temperature. Euchinine has been recommended on these grounds, and from many accounts it appears to have given satisfaction both as an antipyretic and antineuralgic. It shares with quinine the disadvantage of extreme insolubility. Another antineuralgic or antipyretic is a glucoside named kolanine, derived from the kola nut. Other antipyretics which have been described are kryofin and pyramidon. The former is said to be at least as useful as phenacetine or antipyrin, but like these it is not free from the charge of occasionally producing undesirable effects. Pyramidon has been used in typhoid fever and also in some cases of locomotor ataxia. In spite of the introduction of two new antipyretics there can be no doubt that the older methods of cold sponging and baths still remain in favor.

The group of antiseptics has not been materially enlarged. The older remedies are still found efficient and free from objection. Acetanilid has, however, been recommended for local application, while chinisol and airol have also been used as antiseptics. Juniper tar oil, or oil of cade, was not long since recommended as a disinfectant in cholera; careful and extended research has, however, demonstrated that it has relatively weak powers. It has been suggested that in the local treatment of rheumatism oil of wintergreen is preferable to salicylate of sodium, and apart from the greater rapidity of action obtained from the former drug it is said to be free from the liability to produce tinnitus.

Several valuable papers have been published in connection with the treatment of the cardio-vascular system. Foremost amongst these stands an interesting account by Dr. C. R. Marshall of the antagonistic action of digitalis and the members of the nitrite group. In this he furnishes a very useful summary of the actions of digitalis, and

from the experimental side appears to have shown that there is an antagonistic effect on the muscle cells when these substances are used in combination. Further experiments have also been made with digitoxin, which, however, appears to be almost too active for safety. Erythrol tetranitrate, which was introduced by Dr. Bradbury in his Bradshaw Lecture, has in some cases given satisfaction in procuring relief of asthmatic attacks and also of cardiac pain. Pilocarpine has been used for the relief of excessive sweating, although it generally acts as a diaphoretic. Much of a contradictory nature has been written of its value in the treatment of puerperal eclampsia. Many observers maintain that it is a dangerous drug, since it provokes excessive bronchial secretion. It has been suggested that this might be counteracted by the simultaneous employment of atropine.

Creosote, which was formerly much used in the treatment of phthisis, has gradually lost favor owing to its effects upon the stomach and intestines; these discomforts are said to be avoided by the employment of creosotal, which reduces the bronchial secretion, cough, and night sweats. Hydrastis canadensis has been employed in cases of early phthisis and has been found to be an efficient expectorant, while satisfactory results in the treatment of whooping-cough have been claimed for both naphthalene and resorcin. In the paper by Dr. Marshall referred to above the diuretic influence of digitalis was considered. It is somewhat curious to find that strophanthus has lately been recommended as a diuretic, and it is stated that it possesses greater rapidity of action and more powerful diuretic effect, while it is free from the disadvantage of cumulative action or of producing digestive disturbance. The discussion upon diuretics at Montreal was prefaced by two admirable papers which dealt respectively with the clinical and pharmacological aspects and left but little scope for subsequent debate. At the same meeting the diuretic action of *Apocynum cannabinum*, the Canadian hemp, was favorably considered, although it was admitted that it might produce violent emesis and catharsis. These undesirable results were, however, attributed to the admixture of the bitter fiber of the wood with the bark of the root. Salicylate of sodium and caffeine have also been employed for their action on the kidney; the former has been found to check the diuretic action induced by the latter. Small doses of cantharides have been recommended

in acute infectious nephritis, though they are contraindicated in cases of interstitial nephritis. Uremic dyspnea has been treated with ether administered by the mouth and subcutaneously, but it seems only to be of service in cases associated with much pulmonary engorgement. As a laxative for the treatment of chronic constipation in children olive oil has long held a certain degree of favor in domestic medicine; recently, however, it has been urged that it should be employed with a free hand in typhoid fever. Rectal injections of a quarter to half a pint are, if necessary, supplemented by a large breakfast-cupful given by the mouth, and the results claimed for this treatment appear to merit further investigation.

Early in the year we published an account of the treatment of dysentery with *Monsonia ovata*, which is said to exert a specific action distinct from mere astringency. Taka-diasase has been recommended in our columns for some forms of indigestion, and chinaphthol is said to escape change within the stomach and to split up into its constituents in the intestine, where it is credited with local action. Of the list of drugs which have been used in affections of the skin permanganate of potassium in the treatment of lupus, thyroid extract in prurigo, and hypodermic injections of thiosinamine in keloid deserve mention. Tuberculous peritonitis is said to have yielded to the use of creosote in the form of enemata, while injections of glycerin and iodoform into the synovial cavity of the knee-joint are believed to have produced satisfactory results in tuberculous disease of the knee. Thyroid extract has been used with apparent benefit in a large number of different diseases, many of which are devoid of definite pathology. The treatment of syphilis was discussed at some length at the Montreal meeting and allowed scope for detailed remarks on the relative value of different preparations of mercury.

#### ANESTHETICS.

The London *Lancet* of December 25, 1897, after drawing attention to the fact that the year which has just come to a close is the fiftieth anniversary of the introduction of chloroform as an anesthetic, reminds us that the occasion was duly honored by the Society of Anesthetists with a *conversazione* at which an interesting oration on the progress of our knowledge of anesthetics was delivered by the President, Dr. Dudley Buxton. Professor Simpson gave an address in Edinburgh in

commemoration of the first use of chloroform in midwifery by Sir James Y. Simpson. In Tokyo, also, the jubilee of anesthetics was marked by a special meeting and an address by S. Sato, while Ishiguro spoke of the history of the uses of anesthetics in Japan.

Many valuable voluminous papers on anesthetics have appeared during the year, notably one in which Hill carried further his research published in 1897 in the *Journal of Physiology* for May, p. 323. He pointed out that the circulation of the blood depends upon the vasomotor mechanism being intact. The abdominal wall is able to support the veins and so prevents their distention under the hydrostatic pressure of gravity. Muscular contraction during expiration compresses the hepatic and other veins helping to fill the right heart. When the vasomotor tonus is maintained the splanchnic area abrogates the effects of gravity. In vasomotor paralysis gravity at once causes accumulation of blood in the abdominal vessels. This leads to anemia of the brain and the respiratory center is driven to greater activity. Powerful muscular movements take place and blood again enters the right heart. Contraction of the abdominal muscles limits the outflow from the splanchnic vessels. When both the vasomotor tonus and the respiratory pump are paralyzed the circulation cannot be maintained in the "feet-down" position. Chloroform paralyzes both these factors of the circulation. No amount of compression of the abdominal veins will produce paralytic distention of the heart. Both chloroform and asphyxia will do so. Hill finds that such a condition is at once relieved by dropping the patient into the "feet-down" position, as the blood at once flows from the right heart by the force of gravity. The teaching of physiology thus has a practical value and tells us that vasomotor paralysis is a danger to be looked for and provided against as well as the always accepted danger from respiratory paralysis—a condition which Hill finds may arise both from anemia of the brain centers as well as from accumulation of the drug. In the former case the failure of respiration is secondary to the primary cardiac failure.

Wood and Carter undertook a research upon somewhat similar lines and came to rather different conclusions. The fall of arterial pressure, unless very profound, they think does not affect the respiratory center. They admit that if the fall is extreme the respiration will fail, but not otherwise. At

first excessive fall of pressure stimulates the vasomotor center. The circulation recovers itself more slowly after ether than after chloroform. Ether as well as chloroform may cause death some hours after the administration has been discontinued and even after consciousness is present. They regard the effect of chloroform as being more a drug effect than the result of vasomotor influence; and they further think that the after-depression of ether is more severe than that of chloroform. It seems probable, however, that these findings are the result of a fallacy, for they worked with excessive doses of ether when compared with those of chloroform. Hare contends that chloroform kills by vasomotor paralysis. He advocates the use of atropine, bandaging the extremities, compression of the abdomen, and inversion in the event of syncope. Schleich, if we are to accept the evidence of Maduro, has suggested a new and valuable method. His theory is that the anesthetic should have a boiling point as near the body temperature as possible. He has accordingly made three mixtures which have boiling points respectively of 38° C., 40° C., and 42° C., by combining chloroform, ether, and petroleum ether (benzine). The first mixture when inhaled causes a light and transient sleep, the second and third greater and greater depths of anesthesia. The patients are said to be spared all or most of the after-effects of narcosis. No doubt so careful an observer as Schleich has made sure of his ground before he has allowed publication. Meyer (New York) also has employed the method of Schleich for general anesthesia and speaks of its value. It obviates cyanosis, bronchial troubles, and, it is said, does not affect the heart as much as chloroform.

An attempt has been made to trace a causal relation between the temperature, the dampness of the atmosphere, and the death-rate under anesthetics, but it must be confessed that the views enunciated are more theory than proved fact. The subject of anesthetics in obstetric practise has received considerable attention, several papers having been read. Ballantyne draws attention to the fact that the physiological condition of parturition is one marked by hypertrophy of the heart, while the constant contraction of the abdominal and other muscles during labor helps to maintain the circulation. Blood-pressure is thus kept up and even increased, and the respiration is excited. The results of Doenkoff working with

Schatz's tokodynamometer show that although deep chloroformization does lessen the uterine contractions, ordinary narcosis has no effect whatever in that way.

Waller has carried further his important research work commenced some time back, and dealing with the behavior of a detached nerve when exposed to the vapors of various anesthetics. Prolonged series of action-currents caused by tetanization at regular intervals exhibit no diminution—*i.e.*, nerve is practically inexhaustible. When the nerve is exposed to the anesthetics, ether or chloroform, the active currents are temporarily suppressed—*i.e.*, the anesthetics temporarily abolish excitability. Chloroform causes more prolonged suppression than ether, and the suppression is finally absolute—*i.e.*, no recovery takes place. Waller has come to the conclusion that the relation of safety of these two anesthetics is as one to seven—*i.e.*, chloroform is seven times more deadly to nerve-tissue than is ether. The clinical evidence upon this point is usually taken to show that for every one death under ether thirteen under chloroform take place. There seems no reason, however, to regard these figures as necessarily discrepancies, since in the first place the clinical statistics are far from being exact, while there must be obvious differences between the behavior of detached nerve and the nervous system as a whole. Waller's conclusions led him to what he regards as "the chloroform paradox." If, he says, chloroform is a dangerous agent it should only be used in exceptional cases, but if it is as safe as ether, which he denies, any deaths which take place under it ought not to occur, and the persons who are responsible for them must be held to be guilty of culpable carelessness. Waller further examined other bodies with regard to their action upon nerve: Four-per-cent. carbon dioxide increased nerve excitability; in larger quantity it caused its diminution or abolition followed by augmentation—*i.e.*, it behaves like ether. Oxygen, nitrogen, hydrogen, nitrous oxide and carbon monoxide have no effect upon the nerve currents. In reference to the action of carbon dioxide Waller points out that the danger of asphyxial states during the giving of chloroform lies not in the presence of an accumulation of carbon dioxide, but in the accumulation of the chloroform itself.

L. Guthrie, reviewing the subject of "Chloroform Narcosis in Children," finds that children, as far as his experience goes, are affected in precisely the same way as adults and are

therefore quite as liable to the accidents associated with chloroform. Deaths of very young children are perhaps less common than is the case with adults, but it is so simply because children are more easily brought round after overdosage than adults. Their chest-walls are more resilient and their hearts are not as a rule affected by fatty or other degeneration, and hence they respond more effectually to artificial respiration. He gives his experience upon various points. He has never succeeded in chloroforming a sleeping child without awakening it—an important point in medico-legal practise and one illustrated by a recent case of burglary when several persons were stated to have been successfully chloroformed during sleep by the burglar. The conjunctival reflex is not, Guthrie thinks, reliable as a sign of anesthesia in children. Nor does he accept the eye movements as a guide. A moderately contracted pupil, slowly rolling eyeballs, full, deep, regular, somewhat stertorous respiration, slight congestion of the face and lips, regular slow pulse, and no change of these during the progress of the operation are, he thinks, the only reliable signs upon which it is safe to rely. Guthrie also insists that the degree of anesthesia should be varied, accordingly as the different steps of the operation are more or less likely to produce shock.

At a meeting of the Harveian Society (April 29, 1897) the subject of giving anesthetics to children was dealt with, and several speakers referred to the difficulty of judging when a young child was anesthetized. It was pointed out that this drawback did not exist in the case of ether, and its use for young children was recommended. Pollock and Warrington Haward urged the use of ether for children many years ago, and their experience is confirmed by later workers. The employment of the A. C. E. mixture has again been advanced as a useful method in the case of children, and others advocate it both for adults and children as a means of inducing anesthesia, while that condition is maintained by the inhalation of ether well diluted with air. Clement Lucas drew attention to the possible source of infection arising from patients inhaling anesthetics from a dirty face-piece. He believed that pneumonia occurred from this cause. The challenge thus given was taken up by several anesthetists, who discussed the subject at a meeting of their society in March. It was pointed out that pneumonia was a not uncommon complication of surgical procedure in the days before anesthetics came into use.

At the present time such cases were very rare and were probably not traceable to the anesthetic at all. Silk points out that in the years 1894 and 1895, out of 5000 cases published in hospital reports only thirteen cases of pneumonia are noted. All these except one were of septic origin. Prescott, of Boston, had met with three cases of pneumonia out of 40,000 etherizations. Further, both ether and chloroform are destructive to bacillary life. Again, nitrous oxide gas, which is the most commonly given anesthetic, is never the cause of this disease.

With regard to the question of pneumonia following the use of ether, Whitney has found that the pneumonia which occurs is not a peculiar form of the disease; the ordinary pathogenic organisms are present, and the disease follows the normal course. Sternberg holds that pneumococcus is normally found in the mouth. Whitney further suggests that the prolonged use of ether may lower the vitality of the epithelium and enable the organism to exert a specific action. As a prevention he advises that the mouth, nose and pharynx of the patient should all be carefully sterilized before the anesthetic is given.

It is of no small interest to find that two observers, Lemoine and Gallois, have employed ether both internally and hypodermically for the treatment of uremia and nephritis and have met with success. If their results should be confirmed it may prove that the action of ether is after all not so deleterious as has been held by some.

Von Lerber has examined the condition of the blood after ether has been inhaled, with the following results: In 101 cases the blood was examined and the hemoglobin was in the majority of instances unaltered; the corpuscles were found to be but little changed either in number or in appearance, although some leucocytosis was present. Spectroscopic examination of the urine showed no increase of the urobilin. He concludes therefore that ether does not exert any deleterious effect upon the blood.

The statistics of Gurlt for the year are of interest; they comprise 58,769 cases. Of these, 27,029 refer to the use of chloroform with 29 deaths; 19,856 to ether with 3 deaths; 5000 to Billroth's mixture (chloroform, ether, and morphine); 1000 to brom-ethyl; 600 to ether-chloroform with no deaths. The figures for seven years are: 327,500 cases with 134 deaths—*i.e.*, 1 in 2444; and 1 death in 2039 from chloroform.

*THE UNTOWARD EFFECTS OF QUININE.*

A. LAVERAN in an original article in the *Journal des Praticiens* of October 9, 1897, after pointing out that ordinary doses of quinine are usually well borne, passes on to a consideration of the fact that its salts are irritants to the skin if the epiderm is removed, and that they also prove irritating, in concentrated forms, to the mucous membrane of the digestive canal. So much is this so that Broussais has regarded the sulphate of quinine as sufficiently irritating to produce or augment gastritis present in febrile patients, and he even recommended that the physician resort to the use of bleeding and purgatives for the relief of gastritis produced by the drug. This view of Broussais is, however, excessive, and true gastritis caused by quinine need never be feared. The nervous troubles which are most commonly produced by the drug are, as is well known, roaring in the ears, with vertigo. The drug in large doses or when given to persons with an idiosyncrasy is, of course, undoubtedly poisonous. Thus Trousseau and Pidoux report the following cases:

A young nun took in one day about twenty grains of the sulphate of quinine, and on the following day forty-five grains, for the cure of an attack of asthma. Four hours after the ingestion of the poison she had loud noises in the ears, vertigo, and excessive vomiting, and seven hours after the administration of the quinine total blindness and deafness. After this delirium came on and the case required active treatment, but the patient recovered. (*Traité de Thérap.*, 8 edit., t. ii, p. 487.)

Another instance occurred in a vigorous man, the case being reported by Floyer, in which dyspnea and urticaria followed the administration of a very small dose, amounting to only three grains (*British Medical Journal*, 1886).

Rizu reports a case in which the sulphate of quinine in very small doses provoked congestion of the face, severe attacks of orthopnea, and urticaria (*Bull. de la Soc. des Méd. et Natur. de Jassy*, 1887).

Pispiris, of Athens, has also published two cases of intestinal hemorrhage in anemic malarial patients following the administration of quinine (*Galenos*, Athens, August, 1888).

Kobner has seen grave symptoms arise in a child after the hypodermic injection of five grains of sulphate of quinine, and scarlatiniform eruption take place. There was colic

and a bloody discharge from the rectum. (*Bull. Gén. de Thérap.*, 1890, p. 506.)

Grooskopff has also observed grave symptoms after the use of thirty-eight grains of quinine in one dose (*Therap. Monatshefte*, 1892), and a number of instances are on record in which hemoglobinuria has been produced by quinine.

Laveran believes, however, that cases of intolerance to quinine are rarely met with. He himself has never observed, after the administration of sulphate of quinine in the dose of fifteen to forty-five grains in twenty-four hours, anything more than roaring in the ears and fleeting deafness.

On the other hand, Bouchardat (Manuel de Matière Médicale, Paris, 1865, 3 edit., t. ii, p. 392) mentions a case of a patient suffering from malaria who received from forty-five to sixty grains of quinine, with a fatal result, although the patient was an adult male.

Maillot, in a case of pernicious anemia, administered, on the other hand, more than two and a half drachms of sulphate of quinine in twenty-four hours and cured his patient.

Monneret has given two drachms of sulphate of quinine a day for rebellious headache, with good results; and Giacomini has given, without inconvenience, during a period of over forty-seven days, forty-five grains to a drachm of the sulphate of quinine each day. Giacomini also records the case of a man who by mistake took no less than three drachms of the sulphate of quinine in one day without any other manifestations than great depression of the heart and nervous system. These symptoms were, however, combated with success by the aid of stimulants.

Guersent cites the case of a woman who took no less than ten drachms of the sulphate of quinine in one day. There was temporary loss of vision and hearing and the power of speech. The surface became cold and cadaverous, but the symptoms disappeared rapidly. We also find that Briquet has recorded the case of a physician who for the cure of a mild fever administered the enormous dose of fifty-five drachms of the sulphate of quinine in ten days and finally died as a result of it.

Guinon has reported the case of a neurasthenic adult in whom two drachms of sulphate of quinine were taken with suicidal purpose. This dose failed to produce death, but was followed by profound collapse, insensibility, coldness of the extremities, and cyanosis.

The dominant symptoms beyond those just mentioned were deafness and blindness. The deafness was absolute for several hours, but then disappeared. The blindness was not complete until several hours had elapsed after the ingestion of the poison. At first the pupil reacted to light, but seven to eight hours after the poison had been taken it became immovable. The urine at first was markedly increased, but afterwards was abundantly reestablished under the influence of treatment, which consisted in the subcutaneous injection of salt water, washing out of the bowel, and the abundant administration of coffee. The temperature remained normal; the pulse was good, being 120 on the first day and 100 on the second day. It has also been demonstrated by cases reported by Baills (*Archiv de Méd. Militaire*, 1885, t. vi, p. 320), Rosenbusch (*Wiener Med. Presse*, April 13, 1890) and G. Greswell (*The Lancet*, May 1, 1897) that as much as three drachms of the sulphate of quinine may be taken at once by an adult without producing death.

Laveran then reports the case of two soldiers who took this quantity of the drug. Half an hour after the drug was swallowed the patient suffered from violent cramps in the stomach, with vomiting, pallor of the face, disturbed respiration, dilated pupils, feeble, irregular pulse, and partial insensibility, with loud noises in the ears and a tendency to syncope. In other cases patients have been seen in whom quinine produced restlessness, delirium, vertigo, intoxication as from ordinary drunkenness, vomiting, and great depression of the nervous system. Cases are also mentioned by Laveran in which quinine seemed to produce hemoglobinuria, even when given in small doses, the urine becoming either red or black. This accident has been well studied and described by Tomaselli in Italy and by many Greek physicians, among whom may be mentioned Karamitzas, Theophanidis, Pispiris, Pampoukis, and Chomatianos.

Karamitzas reports an instance which he studied where hemoglobinuria followed the administration of only five grains of sulphate of quinine; and Kanellis, Pampoukis, Chomatianos and Moscato have observed similar instances. The following references may be of interest in connection with these names and in connection with additional information not given in this article:

Clin. et Experim. sur l'Hemoglobinurie Quinique," *Progrès Médical*, 1888; Tomaselli, "Sur l'Intoxication Quinique," *Congres de la Soc. Italienne de Med. Int.*, Rome, Oct. 20, 1888; Spyridon Kanellis, *Arch. de Méd. Nav.*, 1888, p. 476; Pasquale Moscato, *Gazzetta degli Ospitali*, 1890, Nos. 17-19; Hare, *THERAPEUTIC GAZETTE*, July, 1892; Vaughan, "De la Quinine dans l'Hematurie Malarienne," *Assoc. des Med. Americains*, 1892; Pasquale Moscato, *Gazzetta Medica Lombarda*, June 8, 1896, and *Giornale Internazionale delle Scienze Mediche*, March 31, 1897; Raoul Dumas, *Arch. de Méd. Nav.*, April, 1897; Grocco, "Hemoglobinurie Quinique chez les Malariques," *La Settimana Méd.*, Jan. 2, 1897.

Clarac (*Arch. de Méd. Nav.*, April, 1896) believes that the rarity of quinine hemoglobinuria necessarily depends upon some individual predisposition, the malarial poisoning simply acting as an added cause, for hemoglobinuria due to quinine is never seen when the drug is administered in full doses during typhoid fever or in acute articular rheumatism. According to Pampoukis hemoglobinuria due to quinine may be avoided by the administration of cinchonine.

Tomaselli asserts that the quinine produces not only the hemoglobinuria, but also ictero-hematuric fever easily confounded with the ictero-hematuric fever of severe infection.

The symptoms of ictero-hematuric quinine fever, according to this author (*Congres de la Soc. Italienne de Medecine Interne*, Rome, October, 1888), are that three to six hours after the ingestion of the quinine the patient is seized with a severe rigor. The pain is felt in the loins and lumbar region and unceasing bilious vomiting may occur. These symptoms constitute the first period of the intoxication and usually last about three hours. They are succeeded by a considerable elevation of temperature, amounting to hyperpyrexia in grave cases. With this rise in temperature abundant hematuria supervenes. The urine is passed frequently and is accompanied by alvine evacuations of a sero-bilious character, and dyspnea is also present. The entire surface of the body may be yellow in hue. The bloody urine contains altered blood, fibrin, cylinders, epithelial cells, and bile pigment. Tomaselli has observed both hematuria and hemoglobinuria, but believes that the latter is the more frequent condition. At the end of twenty-four to forty-eight hours

the attack terminates, defervescence is rapid and may produce collapse. Laveran asserts that this ictero-hematuric quinine fever has never been observed by him, and he seems to seriously doubt whether the quinine is ever responsible for this condition.

In regard to quinine eruptions Laveran states that they are quite commonly seen. Sometimes they are urticarial in character; in others they resemble scarlet fever. Cases of this kind have been reported by Floyer, Rizu, and Kobner.

Witherspoon has observed a remarkable example of quinine scarlatiniform erythema occurring in a woman. Fifteen minutes after the ingestion of the quinine there was intense itching and burning of the skin of the extremities and then of the body. The skin became very red and swollen. There was congestion of the conjunctiva and profuse secretion of tears, edema of the face, and roaring in the ears. The tongue became swollen and the pharynx became reddened; with the scarlatiniform eruption there was headache, nausea, vomiting, and the urine was scanty and high-colored. In the course of a few days the skin desquamated in large flakes as it does after scarlet fever. A similar desquamation took place in the mouth, the pharynx, and the tongue. Other doses of quinine given at other times produced the same effects in this patient.

Feulard reports a case of scarlatiniform erythema before the Société de Dermatologie, February 11, 1897; and James Johnston has reported a case of bullous dermatitis from the same cause. These quinine erythemas are evidently due to individual predispositions, just in the same way that small doses of antipyrin produce these eruptions in certain individuals.

According to de Grissac the exanthema which is produced by the administration of quinine internally is probably due to the irritating action of the alkaloid, a small portion of which is eliminated by the sweat (Guyochin, The Sulphate of Quinine Eliminated in the Sweat as the Sulphate of Quinine, Paris Thesis, 1872), and it is probable that this elimination in certain individuals is more pronounced and that the skin in consequence becomes greatly irritated.

In regard to disorders of vision, the deafness, and amblyopia, Laveran points out that quinine most frequently produces these manifestations if we except vertigo, and it is believed that the vertigo is largely dependent upon changes produced by the drug in the

labyrinths; although, on the other hand, as pointed out by Lermoyez, this drug in cases of lesions in the labyrinth causing vertigo often does great good. Laveran states that quinine amblyopia is very rare, is generally complete and bilateral. A large number of references are given.

Laveran finally concludes his article by discussing the oxytocic properties of this drug. He first points out that certain writers have asserted that the prescribing of quinine to pregnant women after the third month is capable of producing abortion. Petitjean, Delieux de Savignac, Rayer, Merz, Monteverdi, Lewis and Warren have called attention to this fact, and in addition he quotes Chiara, Bazin, and Bertrand. Laveran seems inclined to believe, however, that the abortion in cases where quinine has been given has depended upon the malarial infection, and he quotes Duboue, Cordes, Bonfils and Schwab as stating that quinine is not an abortive agent, but that it has a stimulant action upon the uterine muscle during labor.

[In connection with this article we may perhaps be allowed to call attention to an editorial upon the Untoward Effects of Quinine published some time ago in the THERAPEUTIC GAZETTE, and to one or two Progress items dealing with the same subject. To those who are interested in the subject of the danger of quinine producing malarial hematuria or hemoglobinuria, we may refer to the article by the editor of this journal in the THERAPEUTIC GAZETTE for July, 1892, which consisted in a collective investigation extending over all the southern portion of the United States where malarial fever is prevalent.

In regard to the influence of quinine upon the pregnant uterus, we may refer to another original article in the THERAPEUTIC GAZETTE of July 15, 1897.—ED.]

---

#### REMARKS UPON THE PROPER SURGICAL TREATMENT OF TUBERCULOUS BONE DISEASE.

CABOT (*Boston Medical and Surgical Journal*, Jan. 27, 1898) contributes a valuable paper on this topic. He says that the surgical treatment of tuberculosis of bone is a subject about which it is difficult to generalize, for the varying conditions of the patient and the part affected often call for a corresponding variation of the plan of treatment.

Tuberculosis is an infective process against

the tissues strive to protect themselves various degrees of success in different of the body and in different persons. process by which this protection is obtained is mainly by the formation of a wall of active tissue, more or less dense, about tuberculous mass, shutting it in and preventing its spread through the tissues. When protective effort is of sufficient power to successfully resist the tuberculosis, it does so by thoroughly encapsulating the process, and in that case the masses of bacilli, cells and waste products of the cells are contained within a slowly contracting capsule which undergoes cheesy degeneration until, at last, they may even be changed to chalky concretions.

The success of this limiting effort on the part of the tissues depends in a considerable degree upon the vigor of the individual, so that in tuberculous disease of bone (as is well known in tuberculous disease in the lungs) a decided improvement in the surroundings and habits of the patient may result in about a cessation of the process.

In many cases of bone tuberculosis the patient's reliance must be upon the power of nature to limit the process and must be directed wholly to the patient's general condition, with the added benefit of rest to the diseased part, which our back-braces, trusses and other fixative apparatus promote.

In numberless cases of recovery from tuberculosis in children attest the effectiveness of Nature's cure.

Most that we can hope from operation in tuberculosis of bone is the removal of a focus which is acting injuriously in two ways, first, by interference with the functions of the bone involved; and second, by the infection of the system with poison. The facts elaborated at the seat of disease. Tuberculosis of bone is generally a second-stage disease following some deeper infection. The local therefore is, as it were, only palliative, leaving somewhere the primary focus untouched. This primary focus is situated in the lymphatic system; commonly in the glands connected with the respiratory or digestive organs. It is, also, this primary focus of the disease, well encapsulated, so that when removed, the patient's return to health is rapid and often long enduring. It is interesting to consider what degree of usefulness we can obtain in the re-

moval of these local tubercles. By the amputation of a limb above the seat of disease the removal of the local focus is thoroughly accomplished. Occasionally a localized tuberculosis can be entirely dissected out with a considerable margin of healthy tissue around it. When this can be done without bringing the tuberculous parts in contact with the healthy, of course that will constitute a thorough removal. This is rarely possible in tuberculosis of bone on account of the difficulties of the deep dissection; and almost invariably the parts about are more or less infected with the bacilli during the process of removal. In operation upon joints this is particularly true; for the infected synovial membrane is often very difficult of removal, as it dips in between the ligaments and the surrounding muscles and must be dissected away piecemeal. During this slow dissection the freshly wounded surfaces are in constant contact with the tuberculous material.

Fortunately the tissues are able to dispose of a moderate dose of the poison, so that a removal that is approximately thorough answers almost as well as if it were absolutely so. It is probable that microscopical amounts of tuberculous material which are left behind are actually destroyed and removed by the tissues. Larger portions are encapsulated, and it is interesting to note that these operations, which are followed by thoroughly satisfactory healing, often leave behind them little foci of tuberculous material buried in the cicatricial tissue.

Accepting, then, the position that in these cases the surgeon's operation is necessarily incomplete and that Nature must even afterwards do much to accomplish the cure, it is plain how important it is for the surgeon to do all in his power to improve the patient's general condition and to so arrange his operation as to obviate a long confinement in bed, if possible.

The removal of tuberculous material must be as thorough as it can possibly be made, the bony focus being hunted up and entirely removed. Where possible, a considerable surrounding portion of healthy bone should be removed with it. This is usually accomplished in resections of the knee and elbow, and also in those cases of disease of the hip in which the tuberculous process is confined to the head of the femur. When, however, the pelvic bones are also implicated, this is more difficult of accomplishment.

When tuberculosis attacks bone in their

continuity where it is impossible to remove considerable portions of the bone without seriously interfering with the functions of the part, surgeons usually resort to curetting for the removal of the diseased portions. As these portions are softened, they can usually be quite thoroughly removed with the sharp spoon, and the harder consistency of the surrounding healthy parts gives us considerable help in determining when the diseased portion has been thoroughly removed. After such an operation it is not uncommon to see the surface curetted remain in a carious condition for some little time. This is due to death of the surface of the bone bruised by the instrument. And in some cases the presence of the tuberculous process reinfects the bone and leads to a continuance of the tuberculosis.

In the carpus and tarsus this recurrence of tuberculosis is almost certain to occur. This is doubtless due in part to the comparatively ill-nourished condition of these bones. Surrounded as they are by cartilaginous joint-surfaces, their periosteal envelope, through which they receive nourishment, is comparatively scanty. It is usually well, therefore, to wholly remove any of these bones that are diseased.

In the wrist the functional result after a removal of many of the carpal bones is usually not good, but in the ankle these operations, when undertaken in the young, give excellent results.

This brings us to speak of the effect of age upon our treatment of tuberculous lesion of bone. So great is this effect that we might almost say that the success of treatment in cases of tuberculosis, other things being equal, is in inverse ratio to the age—that is, the older the patient, the worse the prognosis.

It is often a nice question of judgment whether, in a certain patient, to choose a partial operation, as the removal of the diseased tarsal bones, for instance, or to give up any attempt to save the joint and accomplish a thorough removal of the tuberculous parts by amputation.

This same question as between a partial operation and amputation also arises in cases much exhausted by the disease, and many patients will recover after an amputation, which enables them to quickly leave the bed, who would succumb to the long suppurating process following extensive resection of the tuberculous parts.

The importance of getting patients quickly

out of bed and out of doors has been dwelt upon. The local treatment should consist in giving the parts absolute rest and, if possible, applying gentle, even pressure over the whole seat of the disease. In some cases when removal has been very thorough, a complete closure of the wound may be adopted; and some cases of resection will do well when the wound is wholly closed or where only a slight dependent opening is left for drainage for a short time. In other cases where, owing to the difficulties of the operation, removal of the tuberculous parts is less complete, this opening is made not only to provide drainage but to afford access to the parts for subsequent treatment, with the hope of enabling and assisting the tissues to throw off the tuberculous process. This may be done by leaving the bony cavity widely open and packed with gauze, or, in case of a joint, by carrying through it large wicks of gauze.

We have in iodoform a substance which has, in a measure, a specific effect upon tuberculous material. It seems to act by stimulating the tissues to an adequate resistance of the tuberculous material left after operation. In a case of an extensive cavity iodoform is generally applied in the form of iodoform gauze or by the means of setons, which are very useful in the ankle- and wrist-joints. When we have considerable sinuses which it is difficult to reach in the application of gauze, iodoform oil affords a good means of applying the drug to the deeper parts, and often excellent results are obtained by its use.

Even after healing has been accomplished, it is usually important to protect the parts from motion for a considerable time by the application of apparatus, as, if motion is allowed, the disease is apt to reappear.

Sometimes in connection with the tuberculous process in bone we have very large abscesses in the soft parts. When all parts of these abscesses can be reached and thoroughly curetted, it is not uncommon to obtain a complete closure of the greater part of the abscess by stitching its walls together with deep-buried stitches, and if this can be accomplished it is the best method of bringing about a cure. In many cases, however, this thorough curetting is not possible, notably in cases of psoas abscess.

The danger of interference where the operation cannot be thorough is that, if large portions of tuberculous material are left, the infection of the denuded parts which have been curetted rapidly takes place, and this

new invasion of the freshly wounded tissue is often accompanied by considerable hectic fever, so that the patient is rather worse off instead of being improved by the attempt at thorough operation.

There is also considerable danger of infecting the parts with other organisms beside the bacilli and thereby bringing about a fever from infection by other pus organisms. In those cases, therefore, where the whole abscess cannot be thoroughly treated, it is wiser to make a small opening, large enough to allow of the discharge of the tuberculous cheesy masses which exist in these abscesses, and to then be content with the injection of iodoform oil and thorough drainage.

The gradual contraction of the walls of the abscess by reason of the cicatricial tissue surrounding it, and also by reason of the intra-abdominal pressure in cases of psoas abscess, usually brings about a satisfactory condition of improvement, although absolute cure of one of these abscesses is extremely rare.

#### THE SURGICAL TREATMENT OF FIBROID TUMORS OF THE UTERUS.

GOELET publishes a paper under this heading in the *American Journal of Obstetrics and Diseases of Women and Children* for January, 1898. He says the surgical procedures which may be adopted in this class of pelvic tumors are: curettage, division of the uterine arteries, myomectomy, both vaginal and abdominal, and hysterectomy.

Since electricity affords only symptomatic relief in a certain class of cases, and this is not always permanent, its use may be limited to inoperable cases, classing under this head cases where the constitutional condition or cardiac disease prohibits or where the patient refuses to consent to operation. The prejudice against operation for uterine fibroids is being rapidly removed, first, because the mortality of total removal has been greatly reduced, and second, because the feasibility of more conservative procedures has been demonstrated. For instance, an extensive myomectomy, where the uterus is the seat of numerous fibroids, is successfully done to-day and the uterus saved, whereas only a few years back the whole organ was removed in such cases. Again, it has been shown that complete atrophy of certain small tumors of this character may be brought about by permanent obliteration of the uterine arteries, which diminishes their nutrition. The possibility of conservative surgery is appreciated

because the evil results of some of our older methods is pretty generally understood. Hence the author would say the prejudice against operative interference is being removed because surgery is less radical and the mortality of radical operations is reduced.

Of the operations enumerated above curettage may be regarded as a palliative measure only, to be employed for controlling temporarily the hemorrhage, which is often profuse and persistent, and which so rapidly exhausts the strength of the patient. It is to be employed also to overcome the obstinate endometritis when any procedure less radical than hysterectomy is done, such as division of the uterine arteries or myomectomy. It is a secondary but nevertheless an important auxiliary measure which should never, in the author's opinion, be neglected. It is only a temporary expedient against hemorrhagic endometritis, because the endometrium is rapidly reproduced, and, since the same causes which produced this condition still exist and have not been removed, the hemorrhage must sooner or later occur.

Of the method of performing this operation, which is generally regarded as simple, much may be said to advantage. It involves more risk in the fibroid uterus, because the walls may be quite thin in places, or soft and spongy and easily perforated. Again, owing to the irregularity of the cavity it is quite difficult in some cases to make the curettage thorough. The ordinary dilator employed for dilating the cervix is frequently inadequate because it is not sufficiently rigid, especially if the growth is near or encroaches upon the cervix, and because the blades of the instrument are too short to effect dilatation sufficiently far up. Great care should be exercised also to avoid exerting too much force or allowing the instrument to slip and produce laceration.

The ordinary curette is likewise inadequate in some cases, because it is too short and does not reach far enough up into the cavity, and it has not sufficient rigidity to enable the operator to remove all that is necessary.

The irrigator ordinarily used for washing out after the curettage is also too short to reach the full length of the cavity, and the tubing employed for conducting the irrigating fluid is too small to furnish a stream of sufficient force and volume even if the reservoir is placed high.

For curettage of the fibroid uterus, then, special instruments are required, and more

than usual care is necessary, both for safety and thoroughness.

In all of these cases the curettage should be followed by a copious irrigation, with a double-current irrigator, of a hot one-per-cent. solution of lysol to remove clots and débris, and after this a solution of iodine should be used through the irrigator. The strength of this solution may vary with the necessities of the case—from half to an ounce of the compound tincture of iodine to a pint of water. In the author's opinion this is the only way iodine should be applied to the interior of the uterus.

The operation for ligation of the uterine arteries, for the purpose of producing atrophy by depriving these tumors of sufficient circulation and nutrition, has been successful when it has been done in appropriate cases and when obliteration of the vessels has been made certain by dividing them. The author has pointed out elsewhere the fallacy of depending upon simple ligation to effect permanent obliteration of these vessels, chiefly because it is difficult to isolate them so that the ligature will destroy the artery; and if a mass of tissue is included in the ligature with the vessel, it shrinks in consequence of the compression and the ligature loosens. Consequently the circulation may be, and frequently is, restored. This would, of course, fail to accomplish the purpose of the operation.

The technique of this operation is as follows: First, the uterus is curetted, and if hemorrhage has been a symptom it is irrigated with a solution of iodine. Then a traction ligature is passed through both lips of the cervix, by means of which it is drawn well down and over to one side, the patient being in the lithotomy position with a short-bladed perineal retractor in the vagina. A semicircular incision is made through the vaginal roof on one side at the cervicovaginal fold, and the base of the broad ligament is exposed by careful dissection with the fingers, hugging the side of the uterus. When the pulsation of the uterine artery can be detected, a stout silk ligature is passed around it by means of a specially devised aneurism needle or ligature carrier, and tied. Especial care is necessary to avoid including the ureter in the ligature, as at this point it is only half an inch from the uterus. The tissue between the ligature and the uterus is then divided with the scissors, and the uterine end of the artery is then picked up with a pressure-clamp and tied with silk or catgut.

The same maneuver is repeated on the other side. The vaginal incisions are closed by continuous catgut suture and a loose dressing of gauze placed in the vagina. Of course, strict aseptic measures should be carried out, both in the preparation for and during the progress of the operation.

The limitation of this operation to such tumors as may be influenced by cutting off the supply of the uterine arteries is important, and upon this depends the success which may follow. It would be unreasonable to expect very large tumors which fill or nearly fill the abdominal cavity to be influenced materially by this procedure, since the other sources of blood-supply are greatly increased as the tumor develops out of the pelvic cavity. The uterine arteries are not the chief source of nutrition in these cases, as they are when these tumors are smaller. The other main channels of circulation, the ovarian arteries and round ligament arteries, are not only greatly increased in size, but these tumors are frequently fed by new vessels established through adhesions with adjacent organs and structures. When, however, the tumor is small or has not developed above the level of the umbilicus, the uterine arteries furnish the chief blood-supply. Likewise, when a subperitoneal tumor springs from or near the fundus, it gets its blood-supply chiefly from the ovarian arteries, and cutting off the uterine arteries cannot be expected to influence the growth materially in these cases.

This operation should therefore be limited to small interstitial growths which have not developed beyond the umbilicus, and small subperitoneal tumors which spring from the wall of the uterus below the fundus. When the operation has been confined within these limits, and when the author has made permanent obliteration certain by dividing the arteries, complete or almost complete atrophy of the tumor has followed.

Myomectomy ranks deservedly first in the order of conservative operations for uterine fibroids, being radical in its conceptions, though it preserves both uterus and ovaries. Until quite recently this operation had a very limited application and its possibilities were not fully appreciated. For some time past pedunculated tumors have been removed, and occasionally one or two small fibroid nodules projecting above the surface of an otherwise healthy uterus have been also removed by enucleation; but where there were numerous interstitial masses, or even

one large tumor, the uterus was invariably sacrificed together with the appendages. Even now, though the successful possibility of an extensive myomectomy has been satisfactorily demonstrated, there are many uteri being sacrificed every day for small tumors which might easily be removed without the uterus.

It is possible to remove successfully not only one or two but numerous interstitial fibroids, large and small, situated deeply in the uterine wall, shelling them out of their bed, closing the wound afterward by suture, and leaving the greatly hypertrophied uterus to regain its normal condition. The operation is one which requires much more operative skill than hysterectomy, and where it is extensive it is fraught with greater danger on account of hemorrhage and the increased risk of sepsis. Hence the strictest aseptic technique must be carried out. The ligatures and sutures must be applied so as to control absolutely all bleeding and close the wounds in the uterine wall perfectly, so as to avoid dead spaces where blood or serum may collect and undergo decomposition. There is practically no limit to the number of tumors which may be removed in this manner, and though the uterus may afterward resemble a battle-scarred veteran, it is saved to the patient and will subsequently recover and may be a useful organ.

A few points in the technique may be useful to those who are not familiar with the operation. The abdomen is opened by an incision sufficiently large to deliver the uterus with tumors out of the abdomen, when this is possible; the peritoneal cavity is protected by a sterilized rubber sheet or flat gauze pads, and when much bleeding is anticipated a rubber ligature is placed around the cervix. When the uterus cannot be lifted out of the abdominal cavity the intestines must be protected by gauze pads, which wall them off from the field of operation. Sometimes the Trendelenburg position is a decided advantage. In removing pedunculated fibroids a flap is made on either side of the pedicle at its base of attachment to the uterine wall. These flaps are stripped down and the pedicle severed by a V-shaped incision below the level of the surface of the uterine wall. Any redundancy of the flaps is trimmed off afterward. Bleeding vessels are controlled by pressure forceps, and, when necessary, a ligature, but both are to be avoided when possible. Free bleeding will be controlled frequently by the sutures employed for

closing the wound, which may be applied immediately before the removal of other masses is proceeded with, or the wound may be packed tightly with sterilized gauze until all the tumors are removed. In removing sessile and deep interstitial growths the uterine wall over the center is split and the capsule of the tumor is laid open; then the tumor is shelled out of its bed by the fingers or the handle of the scalpel. It is important before closing the wound to trim out all loose tissue which would subsequently slough. Perfect coaptation is absolutely essential, hence deep-buried sutures, preferably of fine chromicized catgut, should be employed; Lembert sutures of the same material or fine silk used for the outer layer closing the peritoneal surface.

Two points must ever be kept in mind—the liability to hemorrhage and sepsis—and every precaution should be taken to avoid both. With care, however, the chance of either may be reduced to a minimum.

Usually this operation is best executed through an abdominal incision, as it affords freer access and permits more accurate work. But when there are only one or two small nodules projecting from the uterine wall low down near the cervix, their removal may be accomplished through a vaginal incision either anteriorly or posteriorly to the cervix, according to their location.

Myomectomy, then, should be the operation of election in all cases where it is possible without entailing too great risk. So strongly is the author convinced of the possibilities of this operation that he believes it is applicable in seventy-five per cent. of the cases where now hysterectomy is generally done.

Submucous fibroids projecting into the uterine cavity may usually be removed through the cervix, but it may prove a tedious and difficult operation if the tumor is pedunculated or detached, on account of the difficulty in dilating the canal sufficiently to permit free access into the uterine cavity. When these tumors are very large, however, and their development causes the uterus to project well up into the uterine cavity, a correct diagnosis of their exact character is not always easy, especially if the cervix is small and the canal is contracted. If a correct diagnosis can be made in these cases, it is not always possible to empty the uterus through the vagina. It is possible and feasible, however, in such cases to empty the uterus through an abdominal incision,

as in Cæsarian section, and leave the uterus behind if the walls have not undergone degeneration, thus saving it. If, then, upon opening the abdomen, either for the purpose of a myomectomy or a hysterectomy, it is found that the tumor is not in the wall of the uterus but within the cavity, the uterus should be delivered through the abdominal incision, a rubber ligature placed around the cervix, the abdominal cavity protected by a rubber dam or pads of sterilized gauze, and an incision made in the anterior uterine wall from the fundus to near the attachment of the bladder opening, into the cavity. If the tumor is pedunculated it is easily removed by severing the pedicle near its attachment. If it is broadly attached to the uterine wall the mucous membrane, with the capsule, is split and the tumor shelled out. Active bleeding is controlled by ligature or by sutures which compress and coaptate the raw surfaces. After the uterus has been emptied the cavity is washed out if necessary, and a gauze drain or rubber drainage tube is carried down through the cervix into the vagina. The incision in the uterine wall is closed by deep interrupted sutures of chromicized catgut, which include the muscular layers down to but not the mucous membrane. Done in this manner there is absolutely no chance of infecting the peritoneal cavity, and there is little or no blood lost. Though this operation may involve more risk than a hysterectomy in the same condition, it is fully justified, since it preserves the uterus, which may subsequently become a useful, functioning organ.

Of hysterectomy there is little to be said except as to its limitation. The author cannot now believe that vaginal hysterectomy for fibroid tumors is necessary or justifiable, since tumors which are sufficiently small to permit of their removal in this manner either may not be interfered with, or, if they are causing trouble, atrophy may be secured by dividing the uterine arteries; or if the condition is not appropriate for this operation, the abdomen may be opened, a myomectomy done, and the uterus saved. The conscientious surgeon would surely not sacrifice the uterus, to say nothing of the unnecessary risk to which the patient would be submitted, when these other channels are open to him. Abdominal hysterectomy for uterine fibroids is ever a justifiable operation in those conditions where other operations are not feasible, and especially when the tumor is so large as to cause great inconvenience from its size,

or where the tumor has undergone degeneration or the appendages are hopelessly diseased.

The technique of this operation has been thoroughly discussed and is familiar to us all. Likewise the pros and cons of supravaginal amputation and total extirpation have been gone over again and again, and there would be nothing gained by repetition here, since the adaptability of either method is pretty generally understood.

---

AN EXPERIMENTAL INVESTIGATION  
INTO THE TREATMENT OF  
GUNSHOT WOUND.

In the *Zeitschrift für Chirurgie*, 47 Bd., 2 and 3 Heft, 1898, TAVEL, following the general plan of experimentation pursued by La Garde, comes practically to the same conclusions—i.e., that extremely virulent bacteria carried by bullets into the tissues regularly bring about infection—and furthermore announces it as a fact that cleansing of the bullet track by antiseptic washing or cauterization is futile in preventing the development of general symptoms. The death of the animals experimented upon occurred when the bullet was fired through infected material and when the wounded part was wrapped in fabric which had been infected.

Following this article of Tavel's is one by KOHLER detailing his laboratory experiments conducted with the idea of discovering what means are likely to prove most efficacious in combating the infection incident to a gunshot wound. Kohler states that we may take it for granted that gunshot wounds are infected, frequently because the bullet itself is not sterile, but usually because in its course through the clothing and skin surface it will necessarily carry germs with it. It is evident, however, that this infection is not necessarily by the most virulent germs, and is often quantitatively slight, so that the tissues themselves, even though they are wounded and devitalized, may be sufficient to inhibit the further development of germs. Kohler in his experiments infected the ends of bullets with germs that are virulent to guinea-pigs. As a result of his work he holds that in the treatment of uncomplicated gunshot wound it must always be remembered that it is possible that the wound may be absolutely sterile, or that it may be but slightly infected and with non-virulent germs, or that it may be abundantly infected with virulent germs.

As to which of these three conditions is present it is impossible to determine at once, hence the earliest treatment should be the application of a sterile bandage for the purpose of preventing secondary infection from without. A reactionless course shows the absence of infection, or a very slight one. When the wound is obviously infected drainage is always indicated. The use of the thermo-cautery, tincture of iodine, five-per-cent. carbolic acid solution, all increase the virulence of the germs which are not directly reached by these agents and encourage the quick development of blood poison. The principle of closing at once all gunshot wounds is an extremely bad one. The simple and uncomplicated ones may be thus treated, but those which are extensive, and especially those into which have been carried portions of clothing, should be drained.

In this relation it is interesting to note that Müller as a result of a research comes to the conclusion that drainage must be regarded simply as an indifferent medium which provides for the discharge of wound secretions. Its importance depends upon the fact that it relieves tension and puts the wound in a favorable condition for healing. Tincture of iodine, he states, is an agent which penetrates tissues and weakens bacteria. The thermo-cautery, whilst destroying bacteria with which it comes in contact, favors the destruction of the tissues. Energetic means employed against the infection of gunshot wounds are useless.

*EXTRAPERITONEAL RUPTURE OF THE  
BLADDER COMPLICATED BY FRAC-  
TURE OF THE PELVIS; REPORT  
OF A RECENT CURED CASE,  
WITH A STUDY OF NINETY  
CASES COLLECTED FROM  
LITERATURE.*

MITCHELL reports the following case in the *Annals of Surgery* for February, 1898:

A Lithuanian woman, aged fifty-two years, was admitted May 20, 1896, to Johns Hopkins Hospital, in the service of Dr. Halsted. On May 19, about 11 P.M., ten hours before admission, she was thrown from a wagon, the wheels passing over the hips and lower abdomen at the level of the anterior iliac spines. On admission at 9 A.M., ten hours after the accident, the pulse was 120; temperature 100° F.; mental condition seemed one of stupor. There was frequent moaning, and when the left hip was moved she cried out with pain. Over the lower abdo-

men and thighs the skin had been scratched and was covered with gravel and dirt; the entire superficial epidermis seemed to have been brushed away, but at no point was the fat exposed. The abdomen was not distended nor tender except over the skin bruises, and there was no muscle spasm nor any evidence of intra-abdominal injury. Catheterization at 10.30 A.M. yielded 140 cubic centimeters of smoky urine, with a sediment of blood-corpuscles; and at 2.30 P.M., four hours later, 160 cubic centimeters of similar urine. On distending the bladder with 500 cubic centimeters of boric acid solution, not more than 250 to 300 cubic centimeters could be withdrawn, and examination by means of a speculum showed the bladder to be quite empty, demonstrating conclusively a rupture. It was impossible to ascertain whether urine was passed before admission, but between admission and operation there was no attempt to void urine, and there was no dribbling.

Dr. Bloodgood operated seventeen hours after the accident, under ether. On opening into the space of Retzius, through the middle line, it was found filled with a large quantity of blood-stained urine, which was not ammoniacal, and there was as yet no sign of inflammation. The peritoneum was pushed up to within four centimeters of the umbilicus, and in the lumbar region almost to the margins of the twelfth ribs. This fluid was carefully sponged out, and the peritoneal cavity opened in the middle line to examine the bladder for any intra-peritoneal opening. As none could be found and there was no fluid in the peritoneal cavity, the peritoneum was closed with a double row of silk sutures. The opening in the bladder was demonstrated by passing a silver catheter through the urethra. It appeared to be about two centimeters to the left of the median line at the level of the pubes—that is, just behind the seat of fracture, which was in the ramus of the left pube. The line of fracture was oblique, and two ragged points projected towards the bladder. The bladder wound was closed with silk sutures, not including mucous membrane. Lateral incisions were then made in both inguinal regions, and the three wounds were packed with bismuth gauze, the upper half of the median incision being closed with two mattress sutures in the recti muscles, and a continuous subcutaneous silver suture. There was no loss of blood, and the pulse was excellent at the end of the operation.

Temperature  $100.2^{\circ}$  F.; pulse 106. Cultures and cover-slips from the extravasated fluid were negative, and there were only a few leucocytes.

The patient passed a fairly comfortable night. From 8 P.M. the day previous until noon the following day she was catheterized seven times, twelve to thirty-five cubic centimeters of urine being obtained each time, amounting in all to 162 cubic centimeters of bloody urine. The gauze on the abdomen was saturated with urine, showing that the sutures of the bladder had not held or that there had been another rupture. Temperature  $102.2^{\circ}$  F.; pulse 106 to 110; respiration 30 to 35; condition of stupor more marked than on admission (3.30 P.M.). Patient placed in bath of water at  $100^{\circ}$  (8 P.M.), and in four hours the pulse was 100 and of better quality; respiration 24, and decidedly improved; temperature  $100.8^{\circ}$ . The condition of stupor was replaced by a much brighter mental state, and the patient looked a great deal better.

The patient was taken out of the tub five days later for four and a half hours, during which time no urine leaked from the wound. There was some pain and a little hemorrhage. Removal of the packing was followed by a rise of temperature to  $102^{\circ}$  F., but no discomfort.

The patient remained almost continuously in the bath for eighteen days, being removed only for an hour at a time to clean the tub, and then crying to be returned. The pulse was good, but there was continuous fever from  $100.5^{\circ}$  to  $101^{\circ}$  F., and on the seventeenth day, after examination and removal of two small pieces of bone from the fracture, the temperature reached  $103.5^{\circ}$ . The packing was taken out May 26 (seventh day). The lumbar wounds closed two days later, and the brush-braze wound had entirely healed. The abdomen was soft and there was no evidence of infiltration beyond the suprapubic sinus. Appetite and general condition good.

At this time there was more or less fever and several shaking chills, the temperature in one instance reaching  $107^{\circ}$  F. Examination of the blood was negative, and there was no leucocytosis. The urine showed a faint trace of albumen and many polymorphonuclear leucocytes. The abdomen was soft and not distended, and nothing could be found indicating any accumulation of pus. Spleen and kidneys not palpable. On irrigation the opening between the suprapubic wound and

the bladder was not large enough to prevent distention of the bladder, and 250 cubic centimeters could be retained. On examination of the suprapubic wound a small cavity was found just to the left of this sinus, and communicating with it by an opening two to three centimeters in diameter. This was thoroughly dilated with the index-finger and packed with bismuth gauze. Extravasation of urine into this cavity probably explains the chills and temperature.

Following the dilatation of the cavity named the temperature fell rapidly, and there were no more chills and no rise of temperature. The patient was removed from the bath on June 28, forty days after the accident. Since then the sinus and bladder have been irrigated daily with boric acid solution, and on July 20 the gauze removed from the sinus was slightly moist with urine. The sinus closed rapidly. Two months after the accident the patient was about in a wheel-chair and fairly comfortable, with the exception of some swelling and pain in the left leg and hip.

Improvement continued progressively until the patient was discharged well on March 3, 1897. She walks without difficulty, and there is no evidence of mobility at the seat of fracture.

Considering the great numbers of surgical cases of all kinds treated in hospitals, neither fracture of the pelvis nor rupture of the bladder is of frequent occurrence; for statistics show that in Berlin in 10,867 surgical cases there were only three ruptured bladders, and in London in 16,711 cases only two. In the Johns Hopkins Hospital, among 7000 surgical cases there have been three ruptured bladders.

It is generally stated that fracture of the pelvic bones compose about one per cent. of all fractures. Either lesion is a serious one, but with the two combined the prognosis is always grave.

The injury is met with much more frequently in men than in women, and most commonly between the ages of twenty and sixty—that is, in the most active period of man's life, when his habits and occupation expose him to violence. Harrison, of Dublin, has thought the greater frequency in men due also to the greater size of the female pelvis, and because of the pad offered by the uterus as a protection to the bladder. In boys the bladder is not as likely to be allowed to become distended, an important factor in the causation of rupture; while after sixty a

man has usually retired from active and dangerous service.

The symptomatology is quite definite. After the accident the patient is usually unable to walk or even to rise from the ground, and is often rendered unconscious, though accounts are given of patients walking some distance. Peaslee reports a case of a man who, with seven fractures and a ruptured bladder, could actually walk a few steps. The subjects often describe a sensation of something tearing within them at the time of accident. They are brought to the hospital in a semi-stupid condition, complaining of intense pain in the hypogastric region, or at the seat of fracture. Many go at once into a state of collapse or coma, from which they never rally, dying in a few hours. A pretty constant and characteristic symptom is a great desire to micturate, with either total inability to pass any urine or the passage of a small amount of blood-stained urine or pure blood. Sometimes, however, urination is not interfered with, and the patient voids perfectly clear urine. These are rare exceptions. Again, the patient may at first pass no urine, but after a time be able to do so. There may be one or repeated shaking chills.

The prognosis has always been grave, though with the progress of surgery the death-rate has greatly lessened. Hippocrates thought rupture of the bladder necessarily fatal, while Galen admitted the possibility of recovery in extraperitoneal injuries. In 1878 Bartels collected 169 cases of ruptures of all varieties, with a mortality of 89.3 per cent., and at that time there was only one recorded recovery in intraperitoneal rupture. Cramer in 1896 gave the mortality for all forms as fifty-four per cent. This drop in the death-rate has been to a large extent due to the improved treatment of intraperitoneal cases. In our ninety reports there were fifteen recoveries, making the mortality 83.3 per cent. Taking only those which have occurred in the last fifteen years, we find twenty-four, with seven recoveries—*i.e.*, a mortality of 70.8 per cent.; so that in extraperitoneal rupture the decrease in deaths has not been so great, and it is still considered a very grave injury and one whose treatment has been rather unsatisfactory. When we consider how likely it is to have only recoveries reported, it is not probable that this estimate is an exaggerated one. In the majority (fifty-five per cent. of the collected cases) death occurred in the first four days, while in the first week seventy-three per cent. died. Those

surviving the first few hours rally from the shock and later show signs of peritonitis or extravasation of urine; the lingering cases die generally of septicemia.

The treatment, therefore, is plainly indicated, *viz.*, immediate evacuation of the extravasated urine and prevention of reaccumulation by proper drainage and suture.

As far as the fracture of the pelvis is concerned little is to be done except to fix the parts, though it is sometimes necessary to remove spicules of bone or wire the fragments together.

To get rid of the extravasated urine has been a simple matter, but the question of efficient drainage seems to have been a difficult one. The earliest cases were treated by hot applications, leeches, and blood-lettings, and two recoveries are reported in fifty-three cases where no other treatment, save these and catheterization, was employed.

In all thirty-seven cases were treated by various operative procedures with a resulting mortality of 64.9 per cent. In many of the recoveries the convalescence has been slow and tedious, with a history of long continued suppuration, and the existence of one or more fistulous tracts for months or years.

Statistics show nothing as to the advantages of early operation, for there were more recoveries where the operation was in the second week. But we know that it is best to operate as soon as possible, and it is a question as to whether these late cases would not have recovered spontaneously by rupture of the abscesses and formation of fistulæ.

The first attempts at operation amounted merely to incisions for extravasation plus a catheter retained in the urethra. Of eight cases so treated, three recovered. The recoveries were cases which had gone on to abscess formation, and all that was done was to open the abscesses.

In 1845 Walker, of Boston, first employed lateral perineal cystotomy in a case of ruptured bladder, and drainage through this incision was successful, and the patient recovered. After that perineal incision and drainage was the favorite method, and in sixteen cases there were four recoveries.

Abdominal incision was employed five times, with one recovery; and then suprapubic cystotomy, with or without a counter incision in the perineum, took its place, and has been up to the present time the ordinary method of dealing with this injury, but of eight patients treated in this way only three recovered.

In three cases, including the present one, the continuous bath has been used to prevent absorption and for better drainage, and all of these have recovered. While the bath treatment of wounds is itself an old one, and has long been known and employed, both in this country and abroad, its application in such injuries as the present one seems to have been gradual, and its great value should be insisted upon.

In 1878 Bartels speaks of "giving baths" to a case in which there was extensive supuration, and the patient got well; but he does not go into details as to the time the patient remained in the baths. In 1891 Rose, after doing a suprapubic operation for rupture, found that ordinary dressings were not sufficient, and says that "therefore the patient was every day put in a continuous bath for several hours without any dressing." This was continued for twenty days, and then the bath was used only every second or third day. The second case in which it was employed was in 1896, by Wiesinger. Here on the seventeenth day an abscess was opened over the seat of fracture, and the patient put in a continuous bath. The abscess was healed on the forty-second day.

It would seem, then, that whether there be merely incisions for extravasation or whether suprapubic cystotomy or perineal section be performed, the best results can be secured by placing the patient in a continuous bath.

While at first patients may object to the bath, probably more from the thought of it than from actual discomfort, they soon grow accustomed to it, and, as has been said, the present patient when removed from the tub cried to be returned.

Dr. Bloodgood has already reported a case of ruptured urethra in which the bath was used with excellent result. It has been used by Schede in cases of extravasation of urine, and last year Puzey, in London, reported two cases of ruptured urethra, which recovered under the bath treatment. Thus it would seem to be especially adapted to this class of injuries, where efficient drainage is so important and so difficult.

The author has collected ninety cases of extraperitoneal rupture of the bladder; eighty-four occurred in males and nearly fifty per cent. between the ages of twenty and forty. As to the causes of the injury, twenty-three were due to crushing by weight falling on the body; twenty-five by being run over by a wagon; twenty-two from falling from a height. Of the total number of cases seventy-

five died—i.e., 83.3 per cent. Fifty-three of the fatal cases died in the first week—twenty-nine on the first day. Eleven cases were operated on within twenty-four hours; four recovered. Of seven cases operated on between two and five days none recovered. Of seven cases operated on within two weeks five recovered. Injuries complicated by multiple fracture in forty-two cases. The mortality of the unoperated cases was 76.2 per cent.; that of the operative cases 64.9 per cent.

#### DISINFECTION OF THE HANDS.

MENGE (*Münchener Medicinische Wochenschrift*, No. 4, 1898), while contesting the claim made by Reinicke, Ahlfeld and Vahle that the skin of the hands can be thoroughly disinfected by mechanical and chemical means, especially by means of washing with alcohol, recognizes the fact that this medium has distinct bactericidal powers, especially in regard to those vegetative bacterial forms which have lowered resistance, and that it infiltrates all the superficial layers of the epithelium. Moreover, from its hardening influence, its power of abstracting water, it retains the more resistant forms beneath the epiderm. The especial advantage it possesses is that it does not act upon the living cells of the body. It is worthy of note, however, that if after a thorough brushing with alcohol the hands are subsequently soaked in water or the fluids of the body, the epidermic layers again become softened, desquamate, and may enable spores or other resistant forms of life to escape into the wound. For this reason the use of gloves is particularly advisable. Those employed by Mikulicz, Zweifel and others are of stockinette and extremely thin. They can be readily sterilized by heat and should be worn by the assistants who handle instruments, handle dressings, thread needles, and perform other work accessory to the operation. They are also satisfactory when applied by the surgeon himself, provided he operates by the dry method. If, however, he employs lotions, or if the operation is such that the gloves are necessarily soaked with the fluids of the body, the skin of the hands becomes wet, the shedding of epithelium takes place, and infection may readily pass through the thin porous substance of which the gloves are made. The objection made against gloves that they lessen tactile sensibility, though tenable, is not prohibitive, since by use the surgeon soon becomes accustomed

to them and since he can discard them at any moment if it should be necessary, as before putting them on his hands should be disinfected exactly as if he were not to wear them.

Fritsch has raised the objection that by the rough surface the gloves more or less injure the living cells, an objection which has also been raised to sponging. This can be obviated by the use of rubber gloves, the main objection to which lies in the fact that they are extremely hot and are readily torn or cut in tying down ligatures, inserting sutures, or operating with a knife.

To provide gloves which will be cheap, easily disinfected, and yet impervious to water, is the object of Wolffler. He states that the requirements of surgical gloves are that they shall be water-proof, smooth, comparatively durable, not hot or irksome to wear, and readily disinfected. To meet these requirements Menge, having thoroughly dried the stockinette gloves, immerses them in a solution made up of 100 parts of xylol and 20 parts soft paraffin, which melts at a temperature of 45°C. This fluid is warm and the gloves are allowed to lie in it for a quarter of an hour. They are then wrung out and dried in a warm oven. Water and the fluid ascites flow from the surface of this glove exactly as from that of a feather. It is not, however, absolutely impervious to liquids. It fits the hand neatly and presents a comparatively smooth surface. It is not easily torn or cut and is comfortable to the hand, since it still remains porous. It can be sterilized by steam under pressure. It is cleansed by using soap and hot water.

Menge states that since alcohol lessens the spaces between the epithelial cells and makes a more compact layer which practically encloses and prevents from escaping germs which may lie in its substance, it would be well for the surgeon not to employ any watery solution after having used the alcohol. To prevent the fluids of the body doing away with the beneficial effect of alcohol, he suggests that after the thorough cleansing the hands should be washed in the paraffin-xylol solution and dried with a sterile towel. The epidermis after this procedure seems almost unaltered, excepting that it is somewhat more shining. Water runs from the surface as it would from oil-cloth, and softening of the epidermis is impossible. Thus the germs which lie in the deeper layers of the skin and are not destroyed by the antiseptic solutions are kept there even though the hands are

soaked in watery media a long time. Of course this does not provide for the bacteria which eventually escape through the openings of the skin glands. This protective coating also serves against the entrance of septic material through the skin of the surgeon's hands. The thin water-proof coating may be removed by rubbing with ether and washing with hot water, alkaline soap, and a brush.

Menge suggests the following method of disinfecting: Thorough mechanical cleansing by means of hot water, alkaline soap, and a brush, careful attention being paid to the nails; after that long-continued softening of the hands in water, then thorough disinfection of the skin by means of a watery or weak alcoholic solution of sublimate, and soaking of the skin in seventy-per-cent. alcohol and drying with a sterile towel, finally pouring a paraffin-xylol solution over the hands and again drying with a sterile towel.

#### TREPHINING THE SKULL.

BRATZ (*Centralblatt für Chirurgie*, No. 3, 1898) calls attention to the fact that the requirements of modern brain surgery demand methods of opening the skull quite different from those commonly employed twenty years ago. The raising of large flaps by the hammer and chisel is open to the objection that a certain amount of concussion of the brain is produced; moreover, in breaking the bridge of bone across there results a certain amount of splintering. The concussion effect can be readily imagined by any one who has had a tooth plugged. A similar jarring of the skull results from the use of the rotary saw. The traction saw devised by Gigli is not open to these objections. This instrument is also strongly recommended by Obalinski on the basis of extensive experience. This method must be recognized as a distinct advance in brain surgery. The author has so used this instrument upon the living and has experimented with it upon the cadaver.

The method is especially to be commended because of the slight amount of bony tissue which is destroyed, the resulting solution in continuity appearing as fine cut. In replacing bone flaps thus formed the fit is exact. Also, the incision through the bone can be made oblique, so that the outer surface of the flap is greater in area than the inner. The operation has the further advantage that the formation of flaps is much more quickly accomplished than by other methods. Obalinski commends the Collin perforator, with

small trephine crown, as the best instrument for making the openings through which the saw is to be passed. This instrument is somewhat complicated in construction and difficult to hold in place. The author has constructed an instrument very much on the principle of a brace and bit employed by carpenters, which he strongly commends. In forming the flaps Obalinski directs that a tongue-formed incision should be made in the soft parts, the periosteum should be raised somewhat, and in the line of the incision—*i.e.*, the line of the bone flap—five to seven small openings should be bored through the bone. Two more openings should be drilled through the base of the flap. With a fine elevator the dura is separated from the bridges of bone lying between the openings by means of a curved probe or a bent cannula.

The Gigli wire is passed beneath the bridge to be divided. By pulling this wire to and fro the bone is separated without the use of force and without the faintest jar of the brain. The fine openings through which the saw is to be passed should be not less than one inch nor more than two inches apart; the cannula and the probe or grooved sound, which is used to guide the Gigli wire, should receive various curves in accordance with the distance to be traversed. To protect the dura, which is likely to be cut in the first movements of the saw, the author uses a wire loop passed from one opening to the other. The opening he makes with a bone drill the size of 28 F. catheter. He runs this rapidly down until the point begins to penetrate through the internal plate; the rest of the clearing is done by a species of rongeur. The saw is drawn through by means of a thread attached to the end of the probe.

*THE CURE OF VESICO-VAGINAL FISTULA  
BY THE FREE DISSECTION OF THE  
BLADDER FROM ITS VAGINAL  
ATTACHMENTS AND CLOSURE  
WITH THE BURIED  
CONTINUOUS TENDON  
SUTURE.*

MARCY (*Journal of the American Medical Association*, Nov. 20, 1897) contributes an interesting paper on this topic. In 1887 the author's attention was called to the ease with which the bladder-wall will reunite after injury, under the most adverse circumstances, when the portion involved is free within the peritoneal cavity. The case upon which he operated at this time was that of a child

eighteen months old, where an abscess in the vicinity of the appendix had resulted in a vesico-intestinal fistulous opening in the appendiceal region.

Laparotomy disclosed two fistulæ of the small intestine, complicated with an opening into the bladder to the right of the fundus. The intestines were freed from adhesions and drawn out of the wound. The refreshed edges of the openings were closed by double lines of fine continuous tendon sutures, which in turn were intrafolded by a second layer of continuous tendon Lembert sutures. After the intestine had been returned, the bladder-wall was freed from its adhesions, and the opening into it refreshed and sutured in double lines of continuous tendon sutures, in precisely the same manner as he had closed the intestinal wounds.

The child made an easy and perfect recovery, with primary union of the openings, and is to-day a strong, vigorous girl. The age of the child rendered drainage of the bladder unsuccessful, but from the first the function of the organ seemed little impaired.

The case was instructive in many ways. Perhaps the most important lesson was the primary restoration of the bladder-wall without the supposed necessary physiologic rest of the organ. The method of applying the first row of sutures in the approximation of the freshened edges, held in even support by means of the continuous sutures, inverted the mucous membrane.

The insertion of the suture in both intestinal and bladder-walls is done as follows: The needle is a fine one, curved upon the flat, with eye near the point, and set in a firm handle, made to penetrate the coats of the bladder or the intestine also, but not through the mucous membrane. It emerges about one quarter of an inch from the line of the opening, and is introduced upon the opposite side at a like distance. The needle is then unthreaded, rethreaded with the opposite end of the suture, and withdrawn. This makes the needle a suture carrier like a shuttle, and holds in even coaptation the included structures in a double loop from side to side (shoemaker's stitch). One stitch follows another in an even continuous seam, until the opening is completely closed. By this side-to-side coaptation, the parts enclosed are held in juxtaposition the breadth of the enclosing loop, while the interrupted suture holds only the width of the suture material. The submucous penetration of the needle buries the suture in healthy vitalized structures, and the

pair of forceps was applied to the same artery about a quarter of an inch farther from the spleen; the tissues between these forceps were then divided with scissors and two more forceps applied, as before, to the next vessel. In this way the gastro-splenic omentum was divided without loss of blood and without undue strain on the pedicle up to the level of the proposed division of the spleen (several arterial branches were left to supply the upper end, which was to be retained). The forceps on the spleen side of the divided gastro-splenic omentum were then laid along the inner surface of the lower end of the spleen, and an assistant raised this end with the forceps so that both surfaces of the spleen were well in view. At the level where it was decided to divide the organ the blood-flow through it was arrested by a continuous ligature used in the following way: A long needle threaded with fairly coarse silk twist one and a half feet long was inserted on the inner or "under" surface about half an inch from the edge or border and passed through the thickness of the spleen, emerging on the outer or "upper" surface about the same distance from the edge; the ligature was drawn through until the ends were equal; the free end was then brought up round the border of the spleen and a "double turn" made with the two ends and drawn as tightly as possible, this "turn" being kept through the spleen on the occluded side of the organ as close to the line of ligature as possible and an eighth of an inch to the "edge or border side" of the turn. This was done in order that the next loop should include the spleen where the needle had previously passed through, so that any oozing along this track should be stopped when the loop was drawn tight. The needle was then repassed through the spleen from the under to the upper surface half an inch further on, and a double turn again taken and drawn tight. Continuing in this way the breadth of the spleen was traversed. A reef-knot was then tied and the ends were cut short. The needle may be passed from the upper to the under surface and the turns made on the under surface, but the way described is the most convenient. The occluded end of the spleen was then cut through close to the line of ligature. Separate ligatures were tied round each portion of the gastro-splenic omentum included in the forceps, any tension on the pedicle being relieved as these were tightened. The peritoneum and the three muscular coats were severally united with contin-

uous sutures, the skin incision not being closed. The whole operation was completed in from fifteen to twenty minutes.

The points in the operation which the writer emphasizes are: (1) Its great facility, especially when the double turn is made by twisting the needle round the free end and so getting this double turn on the needle before drawing tight. (2) The oozing which takes place during the passage of the needle is at once checked by the coarse silk, and stopped altogether when the loop is drawn tight. (3) The section of the spleen was absolutely bloodless, except in one case, where a middle loop had not been tied tightly enough; here bright arterial blood oozed away gently, but a similar ligature at that point, tied tightly, at once stopped the bleeding, which did not exceed one drachm. (4) In no case did the ligature cut through the spleen, a little of the pulp only being expressed as the loops were tightened. In the large majority of Jordan's cases coarse silk was used for the continuous ligature, but in two or three cases stout carbolized catgut was employed. (5) The very low mortality.

In cases of rupture of the spleen which are seen in time for surgical interference, this continuous ligature may be employed to arrest the hemorrhage, but the procedure to be adopted would depend upon the extent and position of the rupture. If the injury be of small extent, surrounding the bleeding surfaces with the continuous ligature may be the best treatment; if of larger extent, it would probably save time and be better to excise the damaged portion in the way described. This ligature will also be found to be of service in hepatectomy and in small ruptures of the liver.

In the experimental investigations carried out, nineteen dogs had the lower half of the spleen excised without a death; three dogs had the upper half removed with one death. None of the dogs in which the lower half was excised appeared to suffer the slightest inconvenience or shock after the operation; they at once ran about unfettered and ate voraciously anything they were given. The three dogs which had the upper half excised suffered greatly and one died from shock. It is the removal of the upper half of the spleen which is in the author's opinion so full of danger, so prolific of shock, and often hemorrhage from some small vessel which has either been overlooked or else has retracted before the ligatures were tied. The removal

of the upper half is more difficult than that of the lower half; many more vessels need ligaturing, including, in some cases, a branch from the phrenic previously mentioned, and which may easily be overlooked with fatal results. This artery was present in two of the three excisions of the upper half and in three of the six total excisions. In man it is also occasionally present. Again, in removal of the upper half greater tension has to be applied to the pedicle, which is a distinct cause of shock. Whether the whole spleen or only its upper half be excised does not affect the present argument. In the six cases of total extirpation before referred to, all the dogs suffered greatly from shock, and there were three deaths, the one already mentioned from marasmus and two from shock. If to these six be added the three in which the upper half was excised with one death, we have nine cases and three deaths from shock, a mortality of 33.3 per cent., the survivors also suffering greatly as compared with the nineteen cases of excision of the lower half with no shock or death. May not this great difference be explained by a consideration of the nerve-supply of the spleen and of the relative damage done to the sympathetic nervous system in each case? for on these sympathetic nerves depend the normal tone of all the abdominal vessels and viscera containing any muscular tissue, and all changes in the caliber of these vessels—paralysis or inhibition of their vaso-constrictor fibers causing an extreme fall of blood-pressure, the animal practically bleeding to death into his abdominal vessels—and sudden death has resulted from a slight blow in the epigastric region or from a draught of iced water interfering with the functions of these nerves. It may be well to consider the blood-supply of the spleen first, as the arteries are surrounded or accompanied by the nerves.

The splenic artery, by its pancreatic branches, supplies the body and tail of the pancreas; the left gastro-epiploic running along the greater curvature supplies both surfaces of the stomach and sends branches to the omentum on the left side, some of which may run on to supply the spleen; other branches to the stomach, the vasa brevia, four to eight in number, are given off towards the termination of the splenic artery, some of these arising directly from the trunk and some from the upper two or three of the terminal or splenic branches. The artery then divides some little distance from the spleen into a varying number, from

five to ten, terminal or splenic branches, which enter at the hilus and ramify in the body of the spleen; some of the upper of these give off short gastric branches. In addition to the above there is often the branch from the phrenic running to and supplying the spleen.

The nerves which accompany these arteries are derived from the solar plexus. This, the largest sympathetic plexus in the body, is built up by the semilunar ganglia, nerves from the lumbar portion of the gangliated cord of the sympathetic, the great splanchnics, and the vagi. Through its secondary plexus it supplies the diaphragm (in part) and all the viscera and blood-vessels of the abdomen. Of these secondary plexuses the celiac chiefly concerns the present argument. This plexus is of large size, derived from the forepart of the solar plexus, is joined by the two small splanchnics, and on the left side is augmented by large direct branches from the right vagus. It then furnishes the coronary, hepatic, and splenic plexuses; the latter, surrounding the splenic artery, is again joined by direct branches from the left semilunar ganglion and the right vagus. It supplies the pancreas and stomach through its pancreatic and left gastro-epiploic plexuses, some of the latter running on to the spleen; it again supplies the stomach by branches accompanying the arterial vasa brevia, and then running with the terminal branches of the artery ends in the spleen. In addition to these nerves there are branches from the diaphragmatic plexus accompanying the branch from the phrenic artery when this is present. During an operation it is impossible, of course, to separate these nerves from the arteries, so that a ligature necessarily includes both. A comparison of the operations may be thus stated:

(a) Removal of the whole spleen necessitates the ligaturing of: (1) The splenic branches or, what is the same thing in effect, the splenic artery and nerves before they divide into their terminal branches. (2) The vasa brevia arising from the terminal or splenic branches; this must be done even if the trunk of the splenic artery itself be divided, or else, with the free anastomoses that exist on the stomach, there will be hemorrhage backwards along these branches; neglect to ligature these arteries is probably the cause of some of the deaths from hemorrhage after the extirpation of the organ. (3) The branches from the left gastro-epiploic and phrenic when present. If these

have been divided close to the spleen, as many as from fifteen to twenty small vessels and their accompanying nerves may be included in the different ligatures on the pedicle. If the splenic artery itself be divided, this number would be reduced by the five to ten terminal branches, but the effect on the nervous system would be the same, the "trunk" of the nerve being involved in place of its branches.

(b) Removal of the upper half necessitates the ligaturing of the same arteries except the lower two or three terminal branches, as many as from twelve to eighteen vessels and nerves being included in the ligatures on the pedicle.

(c) Removal of the lower half can be effected by ligaturing the lower two or three terminal branches only. In the two latter operations there is in addition the continuous ligature across the spleen.

From this it will be seen that excision of either the whole or the upper half of the spleen involves great damage to the splenic plexus with its intimate (threefold) connection with the solar plexus and right vagus; entails direct interference with part of the nerve-supply of the stomach and omentum, and severe indirect interference with the vagi and all the sympathetic nerve-supply of the abdomen; the diaphragmatic plexus is often involved and considerable tension has to be applied to the pedicle, and therefore on the celiac and solar plexus and the vagi, thus augmenting the interference with these nerves. The excision of the lower half entails but slight damage to the splenic plexus, and therefore but slight indirect interference with the solar plexus and vagi; the nerve-supply to the stomach, the omentum, and the diaphragmatic plexus is never involved and but slight tension has to be applied to the pedicle. As shock is due to severe inhibition and exhaustion of nerve function, and the grosser the lesion the greater is the shock that results, this great difference in the amount of interference with the nervous system in these operations is the explanation of the great difference in the amount of shock following them; and in the excision of the whole spleen or of the upper half the resultant shock is due to inhibition and exhaustion of the vaso-constrictor fibers of the abdominal sympathetic, and is probably intensified by great interference with the proper performance of the functions of the heart, lungs, stomach, etc., reflexly by means of the vagi. These considerations would induce

the writer to advise in suitable cases in the human being—*e.g.*, abscess, tumor, or cystic disease confined to the lower half, or in hypertrophy which resists medicinal treatment—the excision of the lower half in preference to that of the whole spleen, as the same object would be attained (the removal of the disease or the enlargement), whilst a considerable portion of the spleen would be left to carry on its function; and further, there would be as a reasonable inference a considerable reduction in the death-rate.

#### TREATMENT OF ACROMIO-CLAVICULAR DISLOCATION.

RHOADS (*Annals of Surgery*, January, 1898) calls attention to the fact that dislocation of the acromio-clavicular articulation is usually described as a dislocation of the acromial end of the clavicle, but following the usual nomenclature of dislocations, it is really a displacement of the acromion process of the scapula, the distal bone being the one usually spoken of as the bone dislocated.

In the great majority of dislocations of this joint, the acromion process is displaced downward and inward beneath the clavicle, the outer end of the latter bone riding on the top of the acromion, and the instances are very few where dislocation of the acromion takes place upward with the clavicle engaged beneath the process. This fact is readily explained when one studies the structure of the joint and the character of the injury usually received. The articular ends of the bones are simply two small plane surfaces that are held in apposition by a capsular ligament which completely surrounds the articular margins, but which is so lax in all positions of the joint that the acromion is not tightly braced to the clavicle. This provision of laxity of the capsular ligament permits of a fair range of motion of the scapula upon the clavicle as the former glides upon the thorax, not only in the forward and backward and upward and downward movements, but also in a rotary direction which is called for in the complex movements of the upper extremity. As the joint is superficially placed, some protection is given to it by the aponeurosis of the trapezius and deltoid muscles, the fibers commingling with those of the upper surface of the ligament, while beneath the clavicle is firmly bound down to the coracoid process by the short conoid and trapezoid ligaments, which have, however, no relation to the joint proper.

In all motions in which the shoulder is engaged, the scapula moves upon the outer end of the clavicle, the latter moving in unison upon the sternum, the function of the acromio-clavicular joint being principally to preserve the obliquely forward direction of the glenoid cavity—that is, if there was no such joint, when the scapula slid forward on the thorax the glenoid cavity and shoulder-joint would point inward, and when the scapula slid backward the shoulder-joint would move outward. The joint, therefore, governs the various movements of the scapula, and keeps the glenoid cavity at all times in a forward position. But in accomplishing this preservation of uniformity of position of the shoulder there is but a small—edge to edge, so to speak—articular function of each bone on which the function solely depends, and when certain forms of injury are brought to bear upon the joint—injuries to which the articulation is always exposed from its superficial relations and its position in the body—a disturbance of these meager joint relations, or dislocation, is easily brought about.

The injury that may produce a luxation of this articular union is a blow of sufficient force on the back of the shoulder, as for example, a heavy weight falling from above and striking the shoulder when the body is bent forward, or the participation in an accident in which the body is hurled forcibly, striking the back of the shoulder against some solid object. If the blow lands on the front of the shoulder, a fractured clavicle usually results, whereas if the blow is struck posteriorly, over the acromion or spine of the scapula, the dislocation under consideration is what generally takes place. A blow over this particular area is, however, somewhat infrequent, which accounts for the fact that in the vast majority of cases the blows which the shoulder sustains generally result in a fracture of the collar-bone. The injury is, however, of sufficient frequency to make it one of the surgical pathological phenomena for which the practitioner must be constantly on the lookout.

The recognition of the luxation is not a matter of serious study, and yet it presents, on first sight, a deformity so akin to that of a dislocation of the humerus forward that an unpractised eye may have some difficulty in determining exactly the precise lesion. The rotundity of the shoulder will be destroyed, and the projection of the overriding clavicle may be mistaken for the apparent projection of the acromion in shoulder-joint dislocation.

When, however, it is remembered that the shoulder-joint is depressed but that its motion is not seriously curtailed—*i.e.*, it is not rigid; that the shoulder-joint is carried slightly forward and inward; that the hand of the injured side may easily be carried to the shoulder of the sound side when the elbow is on the chest; that by following the line of the clavicle the normal relations of this bone with the acromion are disturbed, the clavicle being on top; that there is no marked fossa above the head of the humerus; and that the projection of the clavicle is fully one inch within the line of the humerus—one cannot fail to recognize the actual condition.

The treatment of the luxation will necessarily consist in reduction and retaining the limited articular surfaces in position until union of the torn capsular ligament is established. The former is usually easy, the latter most difficult. Reduction can be effected by pushing upward and outward on the arm, which raises the glenoid cavity and scapula, and by manipulation pressing down the overriding end of the clavicle into its normal position and relation with the acromion. This may be done with or without anesthesia, according to the pain-resisting powers of the patient.

The retention of the bones in position now becomes a matter of some difficulty. Desault's dressing is usually recommended, but it proves inadequate for the purpose, the deformity being resumed after the lapse of a few hours, when bandages have stretched and muscles are relaxed. Stimson's adhesive plaster dressing has the disadvantage of causing erosion of the skin in most patients before ligamentous union takes place, which erosion at least is a source of great annoyance, and the test of the efficiency of the method as a curative agent is rendered rather dubious by the information which accompanies the description: "Recurrence can be readily detected through the plaster by the finger or the eye." In fact, some text-books even go so far as to say the retention of the bone in place after reduction presents so many difficulties that it is not worth while to attempt it. To this, however, we would not readily acquiesce. A method of treatment which has answered admirably in the writer's hands seems to meet all the requirements for obtaining a satisfactory result, and the application may be set forth in the following case:

H. H., aged forty-five, of strong muscular development. While the patient was driving in a carriage the horse became unmanageable

and ran away, upsetting the vehicle and hurling its occupant out into the road. He struck the earth forcibly with the upper and back part of his right shoulder, and when found was suffering from a marked deformity of the shoulder, bruises at different parts of the body, severe pain, and shock. A temporary dressing was applied to the shoulder, and the patient was sent to the writer's care on the following day. On examination, there was found considerable swelling, but not sufficient to occlude a marked prominence of the outer end of the clavicle; the acromion could not be felt, and the shoulder was depressed and approximated to the middle line of the body. There was also an apparent lengthening of the right arm.

The patient suffered such intense pain that the author decided to give him an anesthetic to effect the reduction, and to determine at the same time if there was any fracture associated with the luxation. He called to his assistance Dr. J. C. Brick, and while he anesthetized the patient the reduction was effected by the aid and advice of Dr. J. Chalmers Da Costa, no other lesion being found. A pad was placed in the axilla, and a Desault bandage applied. The following day it was found that the deformity had reappeared, and on being reduced by manipulation, the same dressing was reapplied more tightly. This, too, failed to keep the bones in position, and the patient complained of the pain from the tight dressing. Other dressings were then applied according to prescribed methods, and each day the deformity was found to persist. At the end of a week it was suggested that a strap fastened over the shoulder and drawn as tightly as the patient could stand might prove capable of holding the bones in place, and after again reducing the dislocation and holding the bones in position the writer applied such a dressing.

A wedge-shaped pad of absorbent cotton rolled in a towel was placed under the arm, the apex of the pad being pressed firmly into the axilla. A folded towel of heavy texture was placed across the shoulder so as to make it possible to exert pressure over a broad area at the site of injury, and a strap two inches wide (an ordinary trunk-strap was used in this instance) was thrown across the shoulder and under the elbow, and tightened. A pad of absorbent cotton prevented too great pressure on the elbow where the strap crossed. The strap was drawn as tightly over the shoulder as the patient could well

bear it, the point where pressure was exerted being internal to the joint—*i.e.*, between the articulation and the root of the neck—so as to control both the scapula and the clavicle, and the trapezius muscle, without causing the pain of pressure directly over the site of injury. A single retaining bandage passed under the opposite axilla prevented the strap from slipping off the shoulder. The placing of the wedge-shaped pad under the arm with the broad base downward made it possible to exert pressure on the line which would do the most good—upward, outward, and backward—raising the glenoid cavity and with it the scapula, while the clavicle was pushed downward by the same force and thus prevented from again riding up over the acromion. A roller bandage around the chest anchored the arm and elbow to the side, the buckle of the strap not being covered in, so that the strap could be tightened, if necessary, without disturbing the rest of the dressing.

The skin was prevented from being irritated by strips of cotton properly placed. As the patient became accustomed to the pressure, and the shoulder-pad felt somewhat loose on the day following the application, the strap was drawn several holes tighter, the bones being found, however, to have remained in good position during the intervening twenty-four hours. This dressing was kept *in situ* for a week, the parts being examined daily to see that the bones had not slipped. At the end of a week a hand was inserted under the shoulder-pad and the bones firmly held, the arm being held in a fixed position by an assistant, while the entire dressing was removed and the skin surface bathed. The dressing was reapplied weekly after this for two weeks longer, at the end of which time it was discarded altogether, and a spica of the shoulder substituted for still another week. All dressings were then removed. Some pain was experienced on the side of the neck after the original dressing was discarded, which was probably due to some injury to the nerves constituting the cervical plexus at the time of the accident. This disappeared on massaging the parts daily for several weeks, and the patient is now in excellent condition, having full use of his arm without any pain or deformity in the shoulder. The good result obtained in this case, and the simplicity of the application, would tend to recommend the method as a suitable one in the treatment of this refractory lesion.

## Reviews.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. A Digest Collated and Arranged with Critical Editorial Comments by a Large Number of Collaborateurs under the General Editorial Control of George M. Gould, M.D. Illustrated.  
Philadelphia: W. B. Saunders, 1898.

For all practical purposes this Year-book is the most complete and exhaustive single volume dealing with the advances of Medicine and Surgery which is published in any language. There are, it is true, other year-books, particularly in Germany and France, but none of them are as presentable in appearance nor as exhaustive in scope as is the one before us. Further than this, none of them reflect, so far as we are aware, the personal views of the collaborators who assist the editor, and this expression of personal opinion adds very materially to the interest of the book. As a means of attracting attention to the main topics discussed on each page, the method has been carried out of printing important words in large and heavy-faced type, so that in glancing over the page one's eye immediately lights upon the reference or fact which he seeks. This we believe is a useful method, but it requires very careful editing on the part of those who are reading the pages going through the press, else unimportant words receive undue emphasis. While care may have been exercised in this respect in this volume, in a few instances it is lacking, as for example on page 924, where the subject under discussion and the physiological action of the drug are both in the same size type. Such mistakes are, however, not common. Again, we have found in one or two instances in the index that typographical or other errors have been made, with the result that the topic mentioned is not found upon the page indicated. We also notice that proper names are very frequently abbreviated. As this abbreviation saves practically no space and mars the appearance of the book, it seems to us a mistake to print Jas. for James or Geo. for George. We have mentioned these two minor faults because they are practically the only ones which can be found in the very handsome volume of more than one thousand pages.

A number of changes have taken place in the staff of collaborators, but as a rule those who have taken the place of older friends are equally well known as authorities by the medical profession. We are glad to notice that the pages of the THERAPEUTIC GAZETTE have contained so much valuable material

that it, with the *British Medical Journal*, *The Lancet* and other prominent journals in this country and abroad are frequently quoted.

The book can be cordially recommended to any one who wishes a summary of medicine in all its branches for the past year or eighteen months, and we once more extend our congratulations to the editor, Dr. Gould, on the appearance of another evidence of his extraordinary literary activity.

SEXUAL NEURASTHENIA: ITS HYGIENE, CAUSES, SYMPTOMS, AND TREATMENT. By George M. Beard, M.D. Edited with Notes and Additions by A. D. Rockwell, A.M., M.D.  
New York: E. B. Treat & Company, 1898.

This, the fifth edition of a very well known book, comes to us after a shorter interval than has been the case with previous editions. Many of the profession are already familiar with it. It deals with the nature and varieties of neurasthenia, then with the evolution and relation of the sexual sense, the relation of neurasthenia to other diseases, sexual hygiene, diagnosis and prognosis, the treatment of sexual neurasthenia, and diet for the nervous, and finally, a chapter upon sexual erythism. It is true, as pointed out by the editor, Dr. Rockwell, there are a large number of cases of sexual neurasthenia with or without complications continually presenting themselves to the physician for treatment. It is also true, as he points out, that no one has succeeded better than Dr. Beard in delineating the symptoms or describing the diagnosis and treatment for this class of patients. The book is printed in good large type and is as worthy as ever of professional confidence.

DISEASES AND INJURIES OF THE CONJUNCTIVA, ESPECIALLY THE SO-CALLED GRANULATED LIDS. By John H. Thompson, M.D., Kansas City. First Edition, 1897.

The author prefaces this little book of 200 pages with the statement that "Its purpose is to assist practitioners and students of medicine to recognize and treat the diseases and injuries of the conjunctiva. It is not intended that it shall take the place of any of the excellent text-books. . . . for it is simply a collection of short essays." The intention of the author is a good one. All books well and simply written on special subjects are interesting to students and practitioners, but we regret to say that his intention has not been, in all cases, accomplished. The style he has adopted is so easy and familiar and almost colloquial that the meaning is not always clear. The contents are

too specific for the student and general practitioner, and not sufficiently concise and elaborate for the specialist. A more practical and comprehensive discussion of diseases of the conjunctiva will be found in any of the standard text-books. The phraseology is in discord with the rules of the construction of sentences of any known language. Thus, on page 43: "The patients complain of the light, and some of them of an intolerable itching of the lids, it being almost impossible to avoid scratching them." One of the most commendable chapters is that on injury to the conjunctiva, in which minute directions are given for the management of the trifling, yet painful, traumatisms that most authors deem too insignificant to more than mention. The proof-reading has been careless, and here and there serious typographical errors have crept in. For example, page 34, he says: "A solution of 5 grains to the ounce of distilled water may be applied to the inverted lids." The illustrations are so imperfectly executed that they do not elucidate the text. The book is neatly bound, but in other respects the publisher's work might have been more creditable.

H. F. H.

**TWENTIETH CENTURY PRACTICE.** An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In Twenty Volumes. Volume XIII: Infectious Diseases. New York: William Wood & Company, 1898.

This thirteenth volume of the Twentieth Century of Practice, somewhat smaller than some of its predecessors, is devoted almost entirely to subjects which are not of particular interest to the general practitioner, and contains articles upon Ptomaines, Toxines, and Leucomaines, others upon Infection and Immunity, Water-borne Diseases, the Duration of Incubation and Infectiousness of Acute Specific Diseases, Smallpox, Vaccinia, and Mumps.

As will be seen, some of these chapters are not very closely related.

The article by Dr. Vaughan, on Ptomaines and Toxines, which we have mentioned, is very exhaustive and occupies the first 131 pages of the book. The article upon Infection and Immunity, by Dr. Harold C. Ernst, of Boston, extends from page 131 to 279, while that upon Water-borne Diseases, by Mr. Ernest Hart and Solomon C. Smith, is about 80 pages in length. Dr. Dawson Williams writes upon the Duration of the Incubation and Infectiousness of Acute Specific Diseases, a comparatively brief article, and Dr. Moore, of Dublin, contributes that upon

Smallpox; Brouardel, of Paris, writes upon Vaccinia, and Comby, of the same city, upon Mumps.

We have the same complaint to make about the index of this volume as we had about previous volumes. It is not as complete and thorough as the character of the work deserves.

The fact that this volume is not as interesting to the practitioner as have been some of its predecessors does not militate against the value of the System in general, which is, as it is intended to be, a monumental piece of work, representing the state of Medicine in the latter part of the nineteenth century.

**THE YEAR-BOOK OF TREATMENT FOR 1898.** A Critical Review for Practitioners and Students of Medicine and Surgery.

Philadelphia and New York: Lea Brothers & Co., 1898.

This well known book is compiled by a large number of English physicians and contains much of the useful information which has been accumulated in regard to the action of drugs during the latter part of the year 1896 and most of 1897. It covers the treatment of all affections, both surgical and otherwise, and is completed and indexed by authors and by subjects, which increases its value.

The work has been well done by those who have collected the information which it contains. In a number of instances their comments upon the quotations which they make are of interest and value.

The price of the book is one which places it within the reach of every practitioner, and to those who are unfortunate enough not to be subscribers to the THERAPEUTIC GAZETTE this book will convey to them information which, otherwise, they have missed in current literature.

**THE THERAPEUTICS OF INFANCY AND CHILDHOOD.** By A. Jacobi, M.D. Second Edition.

Philadelphia: The J. B. Lippincott Company, 1898.

Dr. Jacobi has been for so many years one of the leading physicians in the specialty of diseases of children, and one of the leading physicians from every point of view in the profession in the United States, that any contribution from him is certain to obtain the attention which it deserves. That this opinion is based upon fact is shown by the rapid exhaustion of the first edition of his book, which appeared but a little more than two years ago.

To the practitioner of medicine the book possesses an added charm because of the fact

that the personal experience of the writer is reflected on almost every page. Like other books which have authors of Teutonic origin, the text is written in an informal style which makes one feel that he is reading the report of a clinic rather than an essay upon pediatrics. For this reason the book is not satisfactory as a text-book for students. Although it covers less than 650 pages, it deals with diseases of the skin, of the bones and joints, and of the eye and ear in childhood; and this illustrates the fact that no part of the volume can be considered an exhaustive or complete treatise upon the diseases which it considers. As representative of the opinions and practises of a physician of high repute, the book can be cordially recommended as one which will bring its reader closely in touch with his cases.

THE ELEMENTS OF CLINICAL DIAGNOSIS. By Professor Dr. G. Klemperer. First American from the Seventh German Edition. Profusely Illustrated. Authorized Translation by N. E. Brill, A.M., M.D., and Samuel N. Brichner, A.M., M.D.  
New York: Macmillan Company, 1898.

The name of Klemperer is so well known to physicians in Europe and America that anything written by him must attract attention and be worthy of examination. The volume before us is a small octavo of less than 300 pages, in which the elements of Clinical Diagnosis are carefully outlined. The first part of the book is devoted to methods of diagnostic examination, and then we find carefully drawn up but precise directions as to the acute febrile and the acute infectious diseases. Diseases of the nervous system, of the digestive system and of the upper air-passages are then discussed from a diagnostic standpoint. Chapter VI deals with the diagnosis of diseases of the respiratory tract, and Chapter VII with those of the circulatory system. Chapters VIII and IX deal with examination of the urine and diseases of the kidney, Chapter X with disorders of the metabolism, Chapter XI with the diagnosis of diseases of the blood. The twelfth chapter considers animal and vegetable parasites, while Chapter XIII discusses the Roentgen rays as diagnostic aids. Considering the size of the book, this is one of the best diagnostic manuals with which we are acquainted, and should prove as popular among English speaking medical men as it has with our Teutonic brethren; for though we have looked over it with considerable care, we have not found anything that varied from the line of usefulness or accuracy.

HUGH WYNNE, FREE QUAKER. Some Time Brevet-Colonel on the Staff of His Excellency General Washington. By S. Weir Mitchell, M.D., LL.D.  
New York: The Century Co., 1898.

There are few books belonging to fiction which have become more popular during the last year than this novel by Dr. S. Weir Mitchell. This popularity depends first upon the fact that Dr. Mitchell has brought to his authorship the results of careful historical study and has made himself thoroughly in touch with the spirit of the times of which he writes. It is also interesting because one feels in reading it that he is at least to some extent improving his knowledge of the conditions of the United States during, immediately after and just prior to the Revolutionary War. And finally, and most effective of all in the volume has been Dr. Mitchell's ability to make all his characters human and to touch the heart of the reader from time to time with spirited ideas concerning love and war.

This edition of Hugh Wynne is published by the Century Company in two small octavo volumes, well printed upon good paper, and should prove most popular with those members of the medical profession who have not as yet read the book.

Not infrequently medical men wander far afield from the paths of professional literature into those of fiction and poetry, but very few are markedly successful in these wanderings. In this respect, however, Dr. Mitchell is *facile princeps*, and it is a pleasure to find that a member of our guild can at one and the same time be a distinguished physician, an original investigator, and a most successful author of fiction.

ENCYKLOPÆDIA DER THERAPIE. Herausgegeben von Oscar Liebreich unter Mitwirkung von Martin Mendelsohn und Arthur Würzburg. Zweiter Band. II Abtheilung.  
Berlin. August Hirschwald, 1898.

We have already mentioned in various numbers of the THERAPEUTIC GAZETTE during the last three years the earlier parts of this valuable and exhaustive German Encyclopedia. The present volume of 200 pages extends from Glykokoll to Hydronephrose. We note among the contributors of articles to it such well known names as Munk, Mendelsohn, Wolff, Schleich, and Stadelmann.

The object of the Encyclopedia is, as we have stated, to deal not only with things that are directly therapeutic, but with collateral branches in medicine, and much valuable information in regard to common and unusual drugs is contained in the volume.

RUBÁIYAT OF DOC SIFERS. By James Whitcomb Riley.  
Illustrated by C. M. Relyea.  
New York: The Century Company, 1897.

This is a small octavo volume of a little over 100 pages, with an illustration to almost every page, which illustrations serve to greatly increase the interest in the text since they are all cleverly executed and represent the ideas given us in the verses placed beside them. The characteristic *patois* in which the verses are written makes the reading, perhaps, a little more difficult than they would be if written in ordinary English, but there is from beginning to end that rhythm or jingle which has made Mr. Riley's poetry so popular in this country. The opening verses in the way of a preface differ in meter and in style from the main poem. This is the first of the preface:

We found him in the far away  
That yet to us seems near,  
We vagrants of but yesterday,  
When idlest mirth was here,  
When lightest song and laziest mirth  
Possessed us through and through,  
And all the dreamy summer earth  
Seemed drugged with morning dew.

THE RETROSPECT OF MEDICINE. A Half-yearly Journal  
Edited by James Braithwaite, M.D., and Alfred  
Trevellyan, M.D. Volume XVI, July to December,  
1897.

London: Simpkin, Marshall, Hamilton, Kent &  
Company, 1898.

As is well known to our readers, Braithwaite's Retrospect of Medicine has now been before the profession for the long period of fifty-eight years and is to-day as valuable as ever, for it contains in condensed form the best articles which have appeared during the six months from June to December, 1897. All these articles are picked out because of their particular reference to facts of interest to the general practitioner. The present volume is, we think, even better than its predecessors in the practical character of its contents. The book is published in this country from advance sheets sent to G. P. Putnam & Sons, of New York, and still merits the confidence which has heretofore been reposed in it.

ELEMENTS OF LATIN. For Students of Medicine and  
Pharmacy. By George D. Crothers, A.M., M.D., and  
Hiram H. Bice, A.M. \$1.25 net.

Philadelphia: The F. A. Davis Co., Publishers, 1898.

We are told in the preface of this little manual of 242 small octavo pages that it is designed to present within the briefest possible compass those principles of Latin etymology and construction which are essential to the intelligent application of the terminology of pharmacy and medicine. Some

one has said "half the difficulty of anatomy is inherent, the other half is in wordiness." "The trouble with the student is more in the names of things than in the things themselves. He mistakes the one for the other; his head swims, and then he founders in the sea because of his Latin storm." It is with the object of smoothing the billows which threaten the voyage of the medical student, at least in the early days, that this little book has been compiled. It seems to us to fulfil its function admirably, and we trust that it will do much towards increasing the knowledge of medical Latin.

THE CARE AND FEEDING OF CHILDREN. A Catechism  
for the Use of Mothers and Children's Nurses. By  
L. Emmett Holt, M.D.  
New York: D. Appleton, 1897.

As its title indicates, this tiny book of just one hundred pages is a catechism covering the diet of children. It is arranged, as have been some recently published quiz books, in the form of questions and answers, in a manner which reminds one forcibly of the celebrated "Ben Franklin Primer." It contains much valuable information for the persons for whom it is intended, but we do not see that the question and answer form of the text has materially increased its value.

### LONDON LETTER.

BY RAYMOND CRAWFURD, A.M., M.D. OXON., M.R.C.P.  
LOND.

During the past week the influenza epidemic has undergone a slight remission in London, and with the return of colder weather it is to be hoped that the improvement may be further sustained. The character has for the most part been of the gastro-intestinal type, with sudden and profuse watery diarrhea, and vomiting. In one or two instances the symptoms have been so severe as to produce a most alarming condition. Such an epidemic has worked havoc in the Warwick County Lunatic Asylum. At first it was thought that the symptoms were due to some poison in the food supplied to the inmates, and this seemed to be confirmed by the fact that the largest daily incidence occurred the day after a ball had been given in the asylum. It was even suggested that some of the patients who were well enough to be employed in the kitchen had put arsenic in the food. However, it was shown beyond all doubt that they had to deal with

a very virulent form of influenza. There was an intensely acute onset with rigors and generalized pains in the limbs, head, and neck; coryza and pain in the eyeballs were mostly present. This was followed by vomiting and diarrhea. The evacuations in some cases tended to be choleraic in character, and slight jaundice was not uncommon. The temperature was usually very high at the commencement of the diarrhea, but fell rapidly, usually below normal. The crisis of the temperature was usually marked by profuse and exhausting perspiration, leaving the patient in a state of extreme collapse. In cases of this kind an intense urticaria not infrequently accompanies the crisis. The infectious character of the epidemic was demonstrated in several cases by direct communication to others outside the asylum, who had not partaken either of food or drink within its walls. Intestinal antisepsis has not been of much service in these cases.

At a meeting of the Hunterian Society, Dr. Hingston Fox read a paper on the Treatment of Constipation. He recognized two main forms of constipation—the one due to peristaltic disorder, the other due to lodgment of feces in or above the rectum. The latter seems in most cases to arise from neglect of the calls for relief, so that the rectum becomes less sensitive and also less automatic in its action; hence the importance of careful discipline in the habit in early childhood. It is quite useless to treat these cases by constant laxatives, although those that act on the lower bowel may be useful for a while. To regain the lost habit of rhythmical defecation Dr. Fox suggested certain practical rules: (1) Absolute regularity in soliciting the bowels twice daily—that is, after breakfast and in the evening, when fatigue relaxes the sphincter. An evening evacuation is certainly a habit to be cultivated by business men, whose early hours make regular and leisurely defecation an impossibility in the morning. (2) Easy posture. Lauder Brunton suggests the use of a footstool, but in this matter of posture each man must needs be a law to himself. (3) Distraction of the attention. (4) In cases of difficulty, postponement of vesical relief until after breakfast, so as to get simultaneous relaxation of both sphincters. (5) Removal of all local sources of irritation. (6) Occasional small enemata. We cannot but dissent from this last measure in those cases in which the rectum is unduly insensitive. Glycerin enemata and glycerin sup-

positories very rapidly remove the last remnant of automatic activity, and in our experience water enemata are only a degree less harmful.

Dr. Dawson read a paper on the Physical Signs of Stomach Disease and Their Relations to Diagnosis and Treatment. Dilatation of the stomach he considers to be almost always present in chronic dyspepsia, and for this reason he advocates drugs that increase the motor power of the stomach, such as nuxvomica. For anemic dyspepsia he recommends iron and arsenic from the first, with bismuth. For these cases we ourselves have been in the habit of combining the tartrate of iron with liquor bismuthi et ammonii citratis, and with most satisfactory results. When pain is prominent, the addition of a few grains of bromide of ammonium to each dose usually does all that is needful. In cases of chronic dyspepsia with marked dilatation, in which retention of food in the stomach with marked fermentation is the prominent feature, he uses lavage with electricity and massage, and of drugs, arsenic and alkalies.

At the Society of Anesthetists Mr. Alexander Wilson, of Manchester, opened a discussion on the methods of treatment in emergencies under anesthetics. He grouped the remedial measures under six heads: (1) External applications, such as cold, Corrigan's button to the epigastrium, ammonia vapor to the nostrils, which excites respiration merely in a reflex manner. (2) Reflex excitation and respiration by mechanical means—for example, rhythmic traction on the tongue and dilatation of the sphincter ani. (3) Stimulation of the heart by mechanical and electrical means, including actual puncture. (4) Artificial respiration. (5) Measures counteracting circulatory failure, such as posture and transfusion. (6) Drugs, including amyl nitrite, strychnine, atropine, etc.

With regard to the first two classes it is of course necessary that the nervous tissues should have sufficient vitality to convey stimuli. Mr. Wilson considers artificial respiration the most effectual measure for stimulating a failing circulation. It acts in three ways—by removing the anesthetic vapor, by supplying fresh air, and by promoting blood circulation. Inflation and Sylvester's method of artificial respiration are the most efficient, but faradization of the phrenics may be useful in old subjects with rigid chests. Subcutaneous injection of drugs is open to the

objection that for their absorption some degree of circulatory activity is necessary. Schäfer contended that the respiratory, vasomotor and other centers in the medulla were all affected simultaneously by anesthetics. At a certain stage in the action of chloroform blood-pressure rapidly falls; this goes on *pari passu* with paralysis of the respiratory centers, while the action of the heart itself grows weak, probably in consequence of paralysis of the vasomotor center. The effect on the vasomotor center is the most fatal in cases of chloroform poisoning on account of the absence of efficient and ready means of counteracting it. The failure of respiration is comparatively unimportant, for so long as the circulation is well maintained, the very slightest exchange of air is all that is necessary. Schäfer advocates the employment of atropine before giving chloroform as a means of preventing arterial dilatation, which is the cause of the dangerous fall of blood-pressure. He also speaks encouragingly of nicotine and suprarenal extract for the same purpose; the former may be given by intravascular injection or beneath the skin. Suprarenal extract has a very powerful effect on the heart, increasing the rate and force of its beat; and these two substances together should go a long way towards enabling patients to recover from vasomotor and partial cardiac paralysis. Gottlieb has long maintained that the effect of suprarenal extract was mainly upon the motor ganglia of the heart. He confirmed his belief by observations of the blood-pressure in animals in which paralysis of the vasomotor centers had been produced by chloralization. By simultaneous observation of the renal arteries, he ascertained that the rise of blood-pressure did not correspond to any diminution of caliber of the arteries, so that the main effect must be on the heart. Cardiac vigor is revived even when the chloralization is pushed to a degree at which the movements of the heart are imperceptible and no longer registerable by the manometer.

Dr. Purdon, of Belfast, advocates the employment of lactophosphate of lime in acne and furunculosis. He prescribes it either in combination with iron or with cod-liver oil. For the latter he gives the following formula:

Gum arabic, 3 x;  
Water, f 3 j;  
Syrup of lactophosphate of lime, f 3 iij;  
Cod-liver oil, f 3 iv.  
Essential oil of bitter almonds, m iij.

Rub the gum, water and syrup together until a smooth mucilage is made; then add

the cod-liver oil gradually, with constant stirring, and lastly the essential oil of bitter almonds. Thus made each tablespoonful of the cod-liver oil and syrup of the lactophosphate of lime contains four grains of lactophosphate of lime and fifty per cent. of cod-liver oil.

Dr. Wathen, of Clifton, communicated to the Dermatological Society some unusual local effects from the use of iodoform. He and others had encountered attacks of bullous dermatitis of the hands from handling dry iodoform gauze. In treatment of the condition he had found great relief from the firm application of bandages to the fingers, with boracic ointment and occasionally thick gruel, followed by a visit to Harrogate with the use of Aix douche baths. The line of treatment seems somewhat ponderous for a disorder that presumably should have subsided with removal of the cause.

Sir William Broadbent's pronouncement of the fashionable Nauheim treatment will meet with general approval. He considers that its maximum benefit is derived in cases of dilatation of the heart due to such depressing influences as influenza. It often also gives satisfactory results in cases of functional and neurotic heart disease. In valvular disease it is of course useless when compensation is well maintained, and no symptoms are present; when compensation has completely broken down it is not advisable, as rest in bed and suitable treatment of other kind will be more efficacious. In cases of mitral disease, and more especially mitral stenosis, where a bare balance of compensation is maintained and the stenosis is so far advanced that harm would arise from increasing the contractile power of the right ventricle, it may also be of great service. In aortic disease it is not advisable, owing to the risk of syncopal attacks, though when compensation is breaking down and mitral symptoms are present, it may sometimes yield good results; and the same is true of heart failure from adherent pericardium. As we have pointed out elsewhere, it has always seemed to us that much of the disappointment of the Nauheim system has been due to the modes and methods of its employment. It has been religiously retained in the hands of a few professional promoters as a proprietary remedy to be employed only at their instance, and has thus found disfavor in the eyes of medical men at large. With regard to the artificial substitutes recommended in this country, Sir William Broadbent lays it down

that "this treatment may not yield such good results in England as at Nauheim, as apart from the effects of the natural mineral baths there, and the exercises, the change of air and scene, the quiet uneventful life, the early hours and regular meals, together with freedom from all excitement and worry, will greatly contribute to the success of the other remedies."

Mr. Wallis has some interesting remarks on the causes and treatment of anal pruritus in the *St. Bartholomew's Hospital Journal*. The causes are both constitutional and local, and a small local, given the constitutional predisposition, may lead to a severe pruritus. Errors of diet, especially beer drinking, are the root of many cases, and another frequent cause is uncleanness. In the well-to-do classes some wines will be found to have the effect of setting up this local irritation, and other articles of diet, such as tea and coffee. Strumous people with delicate skins and a good deal of hair about the anus are apt to suffer, and sometimes the disorder will be found to be a purely nervous phenomenon. Among local causes those within the bowel include constipation, hemorrhoids, polypi, fissures, fistulæ, threadworms, and simple ulcers. In his out-patient department Mr. Wallis found in more than twenty-five per cent. of the cases a small ulcer on the dorsal aspect of the bowel between the two sphincters, or a little higher. Of causes outside the bowel we have to reckon with eczema, pediculi, and excess of sweat that is not washed away from the part. In treatment the first essential is general and local cleanliness; this with attention to diet and relief of the bowels will often suffice. Bran-baths are beneficial, and Mr. Wallis gives the following directions for their preparation: A large double handful of bran is put in a gauze bag and placed in the bath ten minutes before use. A small amount of pearl ash may be added to the water, which should be as warm as the patient can comfortably bear. The bath should last for twenty minutes, the buttocks being separated as far as possible. After careful drying, the parts should be carefully dusted with a powder containing equal parts of zinc, starch, and boracic acid powder. The buttocks should be well separated by a firm pad of cotton-wool, which should be kept applied closely by means of a T-bandage and should be worn at night-time. It will be well if the overnight bath can be repeated in the morning, and after it a strip of lint, spread with boric ointment, can be worn

during the day and kept in place by a pad and bandage. If a simple ulcer is present, Mr. Wallis recommends stretching the sphincters under an anesthetic, and scraping the ulcer if necessary. Other causes must be dealt with according to the usual methods.

---

#### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

Since our last letter the "affaire Laporte" has at last been brought to an end by the acquittal on appeal of the accused. Thanks to the efforts of Professor Pinard, and also to the pressure of public opinion, the former judgment was quashed and Laporte's conduct was vindicated. Even the counsel for the prosecution was inclined to admit that a physician could not be prosecuted for lack of success in an operation. Dr. Laporte has received about 15,000 francs, as well as the secretaryship of one of the medical societies. Such a result indicates clearly the state of public opinion in the medical world.

Dr. Lermoyez has published an article in which he speaks at length of acute sinusitis of the face and of the necessity of making a rapid diagnosis. This affection in its chronic form is not readily cured even by specialists, but in its first stages a moderately energetic treatment will suffice to prevent a change leading to a chronic condition. Dr. Lermoyez shows by various statistics established by Gradenigo of Turin and Weichselbaum of Vienna that on an average out of five hospital patients one is afflicted with sinusitis. This frequency is due to two principal causes: dental caries or rhinitis, in which case infection takes place either by projection of the pus into the cavity or by propagation. As for dental caries, it is the first large molar which is most readily attacked; it is, moreover, in contact with the maxillary sinus. Another thing to be remembered is that meningitis may result from neglect to cure a relatively simple affection.

Dr. Lermoyez goes on to say that if acute sinusitis is generally caused by catching cold, chronic sinusitis is caused by the physician's neglect. This is due to the fact that most physicians do not recognize this affection in its primary stages. They wait until certain symptoms, such as heat, pain, redness of the cheek, indicate exteriorization of the affection. A thing to be remembered is that in reality two important symptoms allow one to make a rapid diagnosis: the first is the flow

of pus from one nostril—pus which is fetid, as the patient is able to perceive; the second symptom is facial neuralgia—supra- or infra-orbital, dental or epicranial. These two symptoms when occurring suddenly are generally sufficient. Lastly, nothing is easier than to cure a case of acute sinusitis. The principal object is to favor the evacuation of pus, and this is best done by preventing the closure of the natural orifice. Cocaine might be used, but is applied with difficulty by the ordinary practitioner; menthol can be employed much better. Dr. Lermoyez recommends inhalations of a teaspoonful of the following solution: Alcohol (90-per-cent.) 100 grammes, menthol 4 grammes, in a bowl of hot water; this to be repeated every two or three hours. Wet compresses may also be applied on the cheeks or forehead according to the sinus. Another point to be observed is that the first upper large molar should be removed as soon as possible.

At a meeting of the Medical Society of the Hospitals, Mr. Lucien Roques showed a patient who had suffered for three years from intermittent attacks of hemoglobinuria brought on by cold. Applications of ether or ice were sufficient to produce on the spot itself edema resembling urticaria. This spot was localized to the region on which the ether or ice had been placed, and by its coloration seemed to indicate that there had been transudation or a modification of the serum with hemoglobin in solution. The patient showed no signs of hysteria or dermatographism. Such a case was to be compared to similar ones indicated by Courtois-Suffit, Mackenzie, and Joseph.

At the same meeting Drs. Achard and Weil called attention to the fact that a virtual condition of glycosuria may exist where no loss of sugar is to be detected, but in which by the ingestion of sugar the reaction of sugar may be found. Such a condition should be compared to what is seen in Bright's disease where albuminuria may not exist. There would seem to exist a certain class of patients presenting the general aspect of diabetic patients, such as adiposity, arterial indurations, varicose dilatation of the face, hemorrhoids, pulmonary emphysema, frequent epistaxis, hemicrania, and baldness, who when treated by the ingestion of glucose show sugar in their urine.

The discussion at the Academy of Medicine on the use of blisters has continued for several weeks. Dr. Huchard, well known for his works on heart disease, says that

cystitis and nephritis are caused sometimes by blisters, but that these affections are only important or dangerous in old people with chronic nephritis or arteriosclerosis, and blisters should therefore never be used in such cases. Grandmaison has, moreover, shown how disastrous are the results of the use of blisters in tuberculosis. However, Dr. Hervieux has praised the effects of blisters in puerperal peritonitis, where leeches or wet cupping are really as useful, though they cannot be said to cure the effusion.

The great disadvantage of blisters is that they permit the infection of the skin, the natural covering of which is removed. Pneumonia and pleurisy have been treated in some cases by blisters, and the only result has either been a relapse or an increase in the effusion. As the blister produces only a revulsive action, it is as well to use other means, such as cupping or cold. The modification produced in phagocytosis is not peculiar to the use of blisters, but is apparent when cold baths are employed.

In answer to this, Dr. Panas, the celebrated ophthalmologist, said that blisters and other means of revulsion had not as yet quite disappeared from surgery. For instance, in various forms of arthritis, in the treatment of the inflammation of various viscera, the injection of tincture of iodine or of essence of turpentine was often used; small blisters also were often used in ophthalmology. The author cited a case where a temporal abscess produced a complete recovery of syphilitic iritis treated without result by the specific treatment.

Dr. Cornil, the well known pathologist, described the various lesions brought about by the use of cantharidin, the active principle of blisters. There is a twofold action—one on the blood-vessels, which are distended and allow of the exit of leucocytes, and secondly, a granular condition of the cells in the tubes, followed by their desquamation. These various effects indicate well what can be expected when cantharides are used in old people with weak kidneys.

Dr. Robin again called attention to what he had said about the results of blisters on the absorption of oxygen, to which Dr. Huchard objected that the experiments of Röhrig show that the absorption can be increased by other means. But the experiments of Röhrig are defective, and the absorption of oxygen tends to destroy toxins by burning them.

Dr. Jaboulay, of Lyons, cites a certain

number of cases of exophthalmic goitre which he has treated by section of the sympathetic ganglion of the neck. He proposes in some future case to try only stretching, as he believes that the degeneracy produced by section may go too far.

---

BERLIN LETTER.

BY JAMES J. WALSH, M.D., PH.D.

---

It was here in Berlin that Senator first called attention to the benefits to be derived from the salicylates in the treatment of rheumatism. The present position of the prominent clinicians here with regard to the salicylates is interesting. Professor Leyden says very simply of the coal-tar derivatives with antipyretic action that all of them have a favorable influence on the disease—*i. e.*, they are analgesic and quieting, and they reduce the fever. As to which one shall be used depends on the idiosyncrasy of the patient. Some patients react promptly to antipyrin, some to phenacetine or acetanilid, while some are relieved more promptly and effectually by the salicylates.

The order given is about that in which the drugs are employed in his clinic, antipyrin being always administered first. Where none of the coal-tar derivatives do good, and such cases occur, recourse is had to what Leyden calls indifferent remedies. Among these he classes the alkalies. This is quite a comedown for the lauded specific remedy of other days, when every hour of illness was considered dangerous until the urine had been rendered alkaline, and heart complications were supposed to be severe just in proportion to the delay of the alkalies.

Professor Gerhardt says of the salicylates that they undoubtedly often give prompt and efficient relief in rheumatism, but salicylic acid is too hard on the stomach, salicylate of sodium too irritating and depressing to the heart. Antipyrin fulfils the symptomatic indications as to pain and fever quite as well as the salicyl compounds, and has not as many or as serious disadvantages. Except where there are cardiac contraindications, the routine practise in Professor Gerhardt's clinic is to give fifty to sixty grains of antipyrin the first day of an acute attack, and seventy-five grains the next. Usually on the evening of the second day the patient is resting quietly without pain or fever.

In Professor Senator's clinic the salicylates, usually the sodium salt, are administered first.

Professor Senator does not claim that it is a specific, though in many cases it has almost a specific action, and he admits that there are certain cases in which other of the coal-tar derivatives give relief when the salicylates have failed.

At most this is claimed to be only symptomatic treatment. The disease itself is left to Nature to take care of. The etiology of the disease all the clinicians admit is a bacterium. Its nature they are not so agreed about. Leyden thinks it is a diplococcus; Senator that it is a degenerate form of staphylococcus; Gerhardt has no special favorite among the forms, but seems convinced of its microbic origin. All of them seem to be agreed that not all the cases of seemingly frank acute rheumatism are due to the same bacterial cause, any more than that all the cases of acute pneumonia are due to the same microbe.

Between pneumonia and rheumatism a number of striking analogies are pointed out over here. Their tendency to occur in damp weather side by side, one being as it were the equivalent of the other in persons of different constitutions; their failure to protect but rather to leave the patient liable to second attacks; their tendency to occur in epidemic form in unhygienic hospital wards or in barracks; the tendency of their bacterial cause to invade other parts, especially serous membranes at a distance from the seat of the original affection, for the diplococcus and the bacillus pneumoniae have both been found in pure cultures in other organs,—all these similarities make doubly interesting the present identity of views as to therapeutics in their regard.

As said before, the treatment of rheumatism, like that of pneumonia, is merely symptomatic. Local measures play a great part in it, and ice-bags and cold compresses are the favorite applications; the aim being not only to still pain and lower temperature, but to influence the growth of the microbes locally, by making the conditions for growth more unfavorable.

The use of the salicylates locally, as they do not disturb the stomach, and are said not to be so depressing to the heart, while they certainly still the local pain very quickly, is a favorite remedy in a good many clinics over here. Wintergreen oil was at one time used for this purpose, but Professor Pribram, in Prague, has noted that though this is ninety per cent. methyl salicylate, some of the remaining constituents are not indifferent, as

he has got much better results with much less depression, by the use of pure methyl salicylate applied over the affected joints. Enough of the drug is rubbed over the joint so that in twenty-four hours the salicylic reaction may be found in the urine.

For chronic rheumatism Professor Gerhardt employs hot sand baths, an arm or leg being covered with sand at a temperature of 120° to 130° F. It would be practically impossible for patients to stand water this hot, as owing to its high specific heat it parts too rapidly with caloric energy to surrounding objects. In sand these high temperatures are very well borne. The results are strikingly good. Only sodium iodide is employed in connection with them.

Towards the end of last year Professor Neisser, of Breslau (the discoverer of the gonococcus), announced that a new silver compound, protargol, had given him the best results that he had ever obtained in the treatment of gonorrhea. It was an excellent antiseptic with the well known specific antagonism of the silver salts to the gonococcus; it was absolutely unirritating and hence could be used in reasonably strong solutions. Ever since the medical journals have been publishing frequent articles on the subject, nearly all in unstinted praise, and a number of young Americans sojourning in Europe rushed into print with series of cases with wonderful results—"Arbeit statistics" they are called here.

The inevitable reaction is just setting in. Professor von Bergmann, at a clinic the other day, denounced all antiseptic treatment of gonorrhea as illusory, and said he had never found anything better than the old reliable sugar of lead. Dr. Behrend, who has medical charge of the prostitutes of Berlin, and whose experience in gonorrhea is very large, reviewed the contributions of the Breslau school to the therapeutics of gonorrhea at the Berlin Medical Society last week, to the great amusement at least of the older members.

In ten years the whole gamut of the silver salts has been run, each claimed to be a panacea for all the ills caused by the gonococcus. There was nitrate of silver, then argentamin, then aluminol, then for a change ichthyol, then argonin, and now finally protargol. Each of them was heralded from the East as a sure specific, and each, except the last, has fallen into innocuous desuetude. Dr. Behrend has not had the results claimed for protargol, and he has found, notwithstanding its assured blandness, certain un-

pleasant irritative effects. Others at the meeting shared his want of confidence in the new drug; and Finger in Vienna and Lasser here in Berlin both have not had success with it. It is, however, undoubtedly a most unirritating antiseptic and an efficient one. From Paris come some excellent reports of its use in eye cases, and there would seem to be a place for it in the antiseptic treatment of sensitive mucous surfaces in general.

The most promising thing in the treatment of gonorrhea just now would seem to be Quincke's suggestion as to temperature. The gonococcus is extremely sensitive in cultures to even slight variations of temperature. Dogs with a constant temperature of 39° C. cannot be inoculated with gonorrhea, and Finger found that malarial and other patients with a temperature of 40° C. would not take it. Quincke puts a Leiter coil around the penis and brings the temperature up to 40° for twenty-four hours, and has got some very satisfactory results.

In tuberculous joint affections the conservative tendency of German surgeons is very striking. Operative measures are put off until it is perfectly evident that no less radical means are of any avail. Injections of iodoform emulsion ten per-cent. are made, not once or twice, but three, four, and sometimes five, times, in the hope of halting the progress of the disease without recourse to the knife. A popular bit of surgical technique in this matter just now is the taking of a Roentgen photograph of the joint just after the injection of the iodoform. As the salts of iodine, like the salts of the metals, are opaque to the x-rays, a very good idea of the distribution of the iodoform is obtained by this means. As the drug is not soluble in the fluids of the joint and inhibits bacterial growth only by its actual presence on the surface of diseased tissues, it is important that it should be thoroughly distributed over the internal capsular surface and the bony cartilages. As ordinarily injected, however, it needs but a small fringe of diseased tissue to so alter the direction of the injected liquid that most of the emulsified iodoform will be deposited over but a very limited area. The subsequent passive movements and kneading of the joint will only partially overcome the defect of technique. Time is precious in the therapeutics of such cases; the bacillus is ever being buried more and more beneath inflammatory products, out of the way of antiseptics, so that the Roentgen procedure would seem to be a promising one.

### *THE TREATMENT OF SOME SERIOUS AFFECTIONS: BEING THE ADDRESS IN MEDICINE BEFORE THE MEDICAL SOCIETY OF THE STATE OF OHIO IN 1898.*

BY H. A. HARE, M.D.,

Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia.

When I accepted the courteous invitation of your secretary to deliver the address in Medicine before the Ohio Medical Society it occurred to me that I could not do better than to consider a number of topics of a

medical character rather than one general theme. We are met together to discuss those matters which will prove of benefit to us in the practise of our profession, and our object is to go to our homes with clear and distinct ideas as to the methods we should employ in the diagnosis and treatment of disease.

The first subject of which I desire to speak is the proper treatment of typhoid fever, a subject which seems so hackneyed as to be worthy of instant dismissal; yet who of us with experience can claim that the ideal treatment of this malady is as yet discovered? Yet this ideal should not be far to seek, for the mortality of the disease must remain at a

certain point as long as the disease occurs—that is to say, a certain proportion of cases in which great susceptibility to the disease exists, or who receive a very virulent dose of the infection and who come under our care late in the malady, must die as long as we are all mortal. The death-rate from typhoid fever is to-day less than it has ever been, and this decrease is all over the world chiefly as a result of prophylaxis, for by this means the number of cases has been decreased in a manner almost equal to the decrease in smallpox since the use of vaccination. Thus in Munich the mortality from typhoid fever has decreased from 453 per 100,000 in 1858 to 3.4 per 100,000 in 1896 as a result of improved drainage, and in every city in the world this improvement, made *pari passu* with an improved water-supply, has produced results of almost equal degree. These facts I have still further emphasized in a paper read before the College of Physicians of Philadelphia in March last. The decreased death-rate also indicates a decreased severity of illness in those who recover, and thus we find that to-day typhoid fever is with a few exceptions distinctly on the wane as to severity and mortality. This decreased malignancy is not, however, the only cause of the decrease in death-rate, which has fallen from thirty or twenty-five per cent. to about fifteen per cent. or less in this country. It is due to the fact that the medical profession has learned one dominant fact, namely, that while they can modify the severity of typhoid fever by prophylaxis and by proper treatment, they cannot abort it or cure it. To express it briefly, the physician must guide his patient through the storm of his infection as a captain guides his ship. He can relieve dangerous symptoms, protect to some extent certain parts from fatal damage, place the whole system of his patient in a state best qualified to resist the disease; he can prolong it by bad treatment; but he cannot shorten the storm by any direct means. This fact rests upon two others, namely, that the infectious process runs a given course in each case so far as its length is concerned; and secondly, the physician, unlike the captain of a ship, takes charge of his patient not before the storm but after it has in gradually increasing intensity been developing in his patient for two weeks before it has manifested itself, and often for as long a period before its character is recognized. The pathological changes have been produced, and even if they do not progress further the proc-

ess set up must run its course in the case of the intestine, for example, till the glandular changes are completed in ulceration or recovery. Every plan of treatment which has been tried in a sufficiently large number of cases to be studied statistically emphasizes these facts, and is directed to a modification of the symptoms and a protection of the patient against injury and not to a true cure in the sense of specific medication.

In Germany some forty years ago typhoid fever patients were treated by catharsis, emesis, and venesection. To-day the vast majority are treated by the cold bath, which, whatever objections may be raised to it, at least permits the system to combat disease and eliminate toxins without fighting the treatment in addition. Again, good nursing and the recognition that the conservation of energy is absolutely essential for the saving of life aid non-meddlesome methods.

At present there is another plan of treatment largely employed in the treatment of this disease, namely, that by antiseptics. In my belief both the bath method and the antiseptic plan are but gropings in the dark, each possessing a glimmer of the light of truth in them which prevents us being lost. It is a safe rule of practise to take a middle stand in accepting and carrying out any particularly highly lauded plan of treatment of disease. Particularly should the physician avoid routine plans of treatment, for as long as human beings differ in their characteristics and micro-organisms differ in their virulence, each and every patient must be treated by himself, or in other words the treatment must be varied by the necessities of the individual. For this reason the plunging of every patient in a tub of water at 70° F. because he has typhoid fever is not good therapeutics, and so the use of purgatives or intestinal antiseptics in practically unvarying amounts is unwise. All great underlying principles may be right in theory, but they must be so utilized as to meet the exigencies of life. In other words, the cold bath treatment and the antiseptic treatment do good in principle, but they must be suited to the patient before us.

There is not time in this discourse to show how a large part of the low mortality claimed by the enthusiastic followers of either of these plans is in part due to the careful nursing, feeding and stimulation of their patients. I have recently (THERAPEUTIC GAZETTE for March, 1898) seemed to prove that the bath only decreases the mortality about three per

cent. in itself. The chief fault with the adherents of both plans is that they are so well satisfied each with his method that they will not use the other, and nothing is more disastrous to patient and to the success of the doctor than the confidence of the latter that the plan he is using is the best to be found. It may be as good as he knows of, but his business is to find a better one always, or at least to seek for it.

In regard to the antiseptic treatment so called, it has not found general recognition because the grain of truth that intestinal fermentation and germ development is harmful has been surrounded with such a mass of theory not in accord with facts, and its technique has been so varied and so futile or heroic, that the grain of fact is overwhelmed. Intestinal antisepsis in typhoid fever is a good thing, but it is not the only good thing and often not a necessity. So, too, the bath is not the only thing needed or always a necessity. Beyond the use of antifermentative drugs to combat evidences of intestinal disorder, I confess that I have never resorted to this sole plan of treatment for the reasons given; and so, too, with the cold bath I have been impressed with the fact that the full cold bath is not for every one. As I have said before, every one does not need croton oil for constipation or twenty drops of digitalis for a failing heart. The skill of the physician consists in knowing not only the general remedy but the dose. It seems to me, therefore, that in the use of antiseptics and purgatives we should use judgment and not routine, and that the same rule holds true of baths.

It is our duty to understand the great underlying principles of a plan before we try it or modify it. In the case of the bath we find that its antipyretic powers are now recognized as being its least useful characteristics; that the most able hydrotherapeutists not only admit but assert that he who expects to throttle the fever by the use of the bath will be mistaken, and that the benefits to be derived lie in the improvement of the circulation, the overcoming of stasis, the production of leucocytosis, the encouragement of oxidation, and the reactive awakening of dormant and intoxicated venous centers. If these are the desiderata, how are they to be attained? Without doubt in a fairly large proportion of cases, in which the temperature is high and in itself dangerous because of its height, by the use of the plunge we get effects which are most desirable; but there

are conditions of mind and body which are capable of contraindicating the bath just as there may be conditions contraindicating the use of quinine in malaria. Are we then to ignore the contraindication, or are we to allow the patient to suffer for want of these beneficent effects? We are to do neither, but to devise another plan for producing them without the factors contraindicated. This can be done by a modification of the cold bath in such a way as to preserve some of its good and excluding its evil effects, and we find its type in the profusely applied cold sponging. I believe this should be used as follows to produce the effects needed, and just as the bath will prove futile if badly given, so will the sponging: The patient should be placed on a blanket on his own bed, stripped, and the nurse should then apply rapidly over his surface a sponge dipped in water varying in temperature with his reactive power and persistency of temperature. It is my custom in the presence of moderate fever, say of  $102.5^{\circ}$ , to order sponging with water at  $70^{\circ}$ ; if the temperature does not fall readily under this, to use water at  $60^{\circ}$ ,  $50^{\circ}$ , or with ice in it. At the same time that the cold is applied the patient is thoroughly and actively rubbed by another until reaction takes place and the surface of his body is bright red. By this treatment the vascular tone can be as well if not better maintained than if the patient is put in a tub, and no cyanosis and severe shivering occurs. Further, it is possible to properly rub and sponge the great muscles of the back, in which region stasis and bed-sores often form, and it is worthy of note that these parts are not rubbed when the patient is in the tub. The rubbing, or massage, is a very important part of the bath, and if it is not performed both the tub bath and sponge bath are nearly futile. In these cases, when the fever is not marked—that is, as high as  $102^{\circ}$ —sponging with alcohol and rubbing may be used to maintain capillary circulation and improve the nutrition of the connective tissues. We are told by the full bath advocates in this country to tub all cases unless they have hemorrhages or perforation or are far advanced in the disease. It seems very much more rational to suit the needs of each case by modifying the bath, provided we are sure to obtain reaction and overcome stasis and improve nervous tone.

Finally, in regard to typhoid fever let me urge upon your attention the wisdom of giving a more generous diet during the course of this exhausting malady. Surely a pure milk

diet is needlessly scant and loads the stomach with large quantities of liquid. Eggs up to three or four a day, soft custards, arrowroot and thin corn-starch may often be given with advantage, and even meat broths may be used, although they sometimes cause diarrhea and may act as culture media for the bacillus. If Graves' epitaph was to be "he fed fevers," surely typhoid fever is one of them.

Another subject to which we may turn with interest is the treatment of diabetes mellitus. This disease is apparently very greatly on the increase, as I pointed out in a brief paper published about a year ago. The statistics then published showed that the increase seems to be well distributed all over the world, although it is greater in Europe than in the United States. On the one hand the claim has been made that this increase is not real but due to the fact that more careful and competent urinary examinations are made to-day than formerly; on the other hand it is now recognized that glycosuria or sugar in the urine is not diabetes, although it may be—when joined with other symptoms—one of the necessary facts to complete the symptom-complex of the malady. Again, the increasing frequency of the disease is shown by the mortality lists due to this cause and not by the reports as to the frequency of this ailment in living persons. The important thing for us to remember, after recalling the fact that glycosuria in itself is not diabetes mellitus but in some cases a mere overflow of carbohydrate material, is the fact that the malady is a symptom, not a disease in itself. It may arise from a number of causes, and each of these seems widely separated in physiology. This being the case it is not hard to discover why one case will be greatly benefited and another not aided by any particular plan of treatment.

There is not time for me to discuss with you the latest and most probable theories and results in studying diabetes. I wish, however, to call your attention once more to the fact that in that class of patients in which diabetes mellitus is most commonly met with, namely, Israelites, the use of full amounts of opium in conjunction with careful regulation of the diet seems very efficacious in a fairly large proportion of cases. The notes of one case in particular will be of interest in this connection, the more so as they illustrate how patients suffering from true diabetes mellitus can not only obtain good results from the use of large doses of

opium, but also utilize the drug in the system to such an extent as to have almost none of the evidences of its action.

J. M., a Hebrew, aged forty-seven; a salesman. His past history was uncertain. He stated he had had a great deal of trouble recently. His present trouble commenced about seven or eight months ago, when he noticed that he had a great thirst, and drank large amounts of water; he also passed a large amount of urine and his appetite increased greatly. He has lost about thirty pounds in weight since his trouble began. He complains of swelling in his feet and is very weak. For the past three or four days his bowels have been very loose. Patellar reflexes absent entirely, and Argyle-Robertson pupils absent. The ophthalmoscopic examination was negative. The media were clear and the eye grounds were normal. An examination of his urine revealed a specific gravity of 1040; color pale; reaction acid; urea eight grains to ounce; sugar eight and a half grains to ounce; no albumen. The amount of urine passed in twenty-four hours varied from sixty-four to seventy-four ounces.

January 25, 1898. He was put on a diet consisting of eggs, meats, chicken, and milk; and the examination of the urine on February 7, 1898, showed that he passed forty ounces in twenty-four hours, with a specific gravity of 1040, and that the sugar had been decreased to 2.67 grains to the ounce.

The gain so far was of course the result of strict diet. He was now placed on ascending doses of opium amounting to one grain three times a day, to be gradually increased.

On February 12 a urinary examination showed sugar 2.29 grains to the ounce. February 17 he was taking three and a half grains of opium three times a day, and the urine when examined showed sugar 1.78 grains to the ounce and otherwise negative. On February 20 urine examination showed sugar 1.6 grains to the ounce; otherwise negative. On February 24 urine examination was negative; no sugar apparent. On February 26 there was noted a slight return of patellar reflexes, and on February 27 the urine examination was negative in result. He was then taking six grains of powdered opium three times daily. On March 3 urine examination was negative; taking seven grains opium three times a day. And on March 4 urine examination showed a specific gravity of 1020—acid; no sugar or albumen. At no time was there the slightest sign of the physiological action of the drug in any part of the

body, save in the decrease and disappearance of sugar.

The development of aneurismal growths involving the larger vessels has been for many years a source of much distress to medical men, not only because the condition is in itself very grave, but also because it has been one which we have been practically unable to control. The gradual increase in the disease process, the constant distress of the patient in body and mind, and finally the inevitable death from rupture, all render such cases worthy of our pity and of every effort capable of producing cure. It is true that such cases are not always rapidly fatal, but the writer has seen only one instance of aortic aneurism which reached large dimensions in which the patient's life has been prolonged for years and with the power of following her ordinary occupation.

Because of the inevitable fatal ending of these cases surgeons have resorted to many different and heroic measures for their relief, such as the injection of irritants into near-by tissues, the introduction of horsehair or other foreign bodies into the sac, and the passing in of a long platinum needle through which was passed an electrolytic current. All of these measures have failed to produce desirable results and some have done actual harm. There seems to be only one non-medicinal moderately safe and rational method of dealing with aortic aneurism, namely, the method originally devised by Coradi and which has been employed in fourteen cases up to the present time, my own patient being the fourteenth. When we consider the great fatality of aneurism of the aorta, the many accidents which may occur to such patients, and the impossibility of knowing beforehand the exact size and shape of the aneurismal sac, the fact that no one of these fourteen cases has died during the operation is remarkable, and the prolongation of life in a number of them may be said to have thrown much credit upon this procedure. This consists in passing into the sac through a hollow needle a number of feet of wire which has previously been perfectly drawn so that kinks do not readily form in it. The wire is first wound around a small glass spool, so that when it is removed from the spool it will speedily coil up again. After a number of feet have been introduced according to the size of the sac, the wire is attached by its external end to the positive pole of a galvanic battery, while a large wet clay electrode is placed on the abdomen or on the small of the back. By means of a

rheostat the current is now gradually turned on to the amount of about twenty milliamperes, at which strength it passes for about ten minutes. After this the current is gradually increased until about seventy milliamperes are passing, and this may be continued for about one hour. The duration depends, however, upon the signs presented by the aneurism and the patient. If it is evident that the process of coagulation of blood about the wire is well advanced early in the operation, the current is not continued as long as if clotting goes on slowly. As a rule, within an hour or even half an hour, the needle is found to be partly fixed or at least not to be so freely movable by the fingers of the operator or the blood stream itself, and this of course indicates that the clot is holding it in place. The following is the history of my patient, which, as it covers many of the important points connected with the operation, is worth reading:

A man aged forty-six entered my ward in the Jefferson Medical College Hospital early in February, 1898. He has an old specific history, a history of muscular strain and of a bad burn. On admission he suffered from pain, dyspnea, and cardiac disturbance. The pain was typically cardiac and radiated down his left shoulder and arm. On examining his chest a well marked bruit was heard over the entire præcordium and well over to the right and left, and the points of greatest intensity of thrill and bruit were found in the second left intercostal spaces anteriorly. At this point auscultation revealed a loud bruit unmistakably aneurismal, and palpation showed the characteristic expansile pulsation. No marked physical signs could be developed posteriorly. A diagnosis of aneurism of the latter portion of the transverse and beginning of the descending aorta was made. He now developed a brassy cough and was slightly hoarse. Later his sputum was tinged with bright blood, and the pain in the eroded ribs became excessive. As the patient had not improved under the use of ascending doses of the iodide of potassium, combined with aconite to lower arterial tension and quiet the action of the heart, and as the persistently bloody sputum seemed to indicate that the growth was perhaps about to rupture into a bronchus, I advised him to submit to the introduction of wire and the use of electrolysis, although he was informed of its danger and possible failure of doing good.

To this proposition he consented, and on Thursday, March 3, before my class, I per-

formed the operation with the kind assistance of Dr. D. D. Stewart, who has now done the operation a number of times. The skin over the aneurismal sac was first prepared for the operation by being sterilized. A few drops of a solution of eucaïne were next inserted under the skin over the sac to produce dermal anesthesia, and then a gold needle hollowed out like a large antitoxin needle was passed directly into the sac. As soon as it entered the sac blood spurted from it freely, showing that the puncture had been a true one. Fine gold wire was now passed slowly into the sac through the cannula until nine feet had been introduced, when the external end of the wire was attached to the anodal pole of a battery and the current turned on, at first twenty, then forty, and finally seventy milliamperes. Very shortly after the stronger current was applied the needle was seen to be moving less freely, and on testing it with my fingers I found that it gave the sensation of being partly fixed at its internal tip. At the end of an hour and twenty minutes the current was stopped and the needle carefully withdrawn, no flow of blood taking place. The wire was snipped off close to the skin and its end pushed under it. For several hours after the patient was slightly shocked, largely because of his nervousness before and during the operation. After this he speedily rallied, and the next day almost all the bruit had disappeared, until in forty-eight hours it had all gone. The expansile pulsation was also greatly decreased and the thrill much lessened.

I should have stated that care must be taken that the needle is perfectly insulated, as otherwise the skin about the entrance of the needle will slough badly.

The subsequent history of the patient is as follows: Five weeks later the patient is recorded as having been sitting up in a chair by the side of his bed for the past ten days. The expansile pulsation and thrill have entirely disappeared, and the impulse in the second left intercostal space feels like the apex beat would feel if displaced. The bruit has entirely disappeared, and only a double aortic murmur is to be heard. The area over which these murmurs are heard is less than one-half that in which the bruit was heard before the operation. There has been no blood spitting. Cough has ceased. The patient now walks to and from the bath-room with ease. He has had at times severe pains in the chest, which he thinks were chiefly due to "the wire stick-

ing in his skin." He has no dyspnea and no loss of voice. It is now eight weeks since the operation and he continues to improve. The result so far is certainly very promising.

Finally, let me call your attention to the following case operated upon by Stewart in 1893, which lived till the early part of 1897, then died of pneumonia. He was repeatedly under my care in my wards in the winter of 1895 and 1896, and while there I had the pictures taken which I now hand to you, and which I utilized in my book on Diagnosis and in an editorial, on a case of this character reported by Hershey of Colorado in the THERAPEUTIC GAZETTE for September, 1896. The large size and great erosion in this sac, which made death seem imminent and inevitable when the operation was done, certainly greatly prolonged his life, made him comfortable, and relieved him from suffering entirely.

It is manifest that a large proportion of these cases cannot be benefited by any measure, but if we can save even a small percentage of patients suffering from an otherwise fatal malady it is certainly worth trying, particularly as they may return to work and usefulness, as for example in Noble's case of abdominal aneurism operated upon after celiotomy had been performed.

At the risk of being accused of harping upon one topic too continuously I wish to call your attention to two methods of treatment which are in my experience distinctly palliative if not curative in pulmonary tuberculosis. The first of these is the use of camphoric acid in the treatment of night sweats. It has proved so constantly serviceable in my hospital wards and practise for a number of years that I am anxious to see its use more general. If given long enough before the sweat to permit of its absorption, so that its effects may be well exerted, it gives results far better than any other antiodorific with which I am acquainted, if given in cachet in the dose of ten to twenty grains. Even larger doses may readily be used. A very important fact is that it seems devoid of any disagreeable action and does not arrest the other secretions of the body as does atropine.

The second remedy to which I wish to call your attention is the oil of cloves given, by the mouth and hypodermically, for the purpose of decreasing cough and expectoration in advanced pulmonary tuberculosis. Of this treatment I have spoken before, and my further experience confirms my favorable

opinion of it. The use of the oil hypodermically in the dose of five drops mixed with thirty to sixty minims of the best French olive oil, sterilized, is productive of considerable local pain for a number of minutes, but the anesthetic properties of the oil soon overcome this and patients tell me that the relief from cough more than repays them for the pain. The injection is given once a day into the loose tissues of the back. For its simultaneous internal use it is best given an hour after meals in five-, ten- or fifteen-drop doses. These doses must be used with caution as the oil may disorder the stomach. Not only is the cough and expectoration greatly decreased, but the sweats and hectic fever are generally modified to a very great extent.

Last, but not least, in this brief review of some of the less common remedies, let me say a few words in regard to the value of camphor as a general diffusible stimulant in exhausting diseases and for the same purposes in medicine as we commonly employ strychnine at this time. Graves, of Dublin, regarded it as one of the best remedies we possess for the prevention or relief of collapse, and yet the profession has, in its search for new things, given it far less attention than it deserves. It has been found of great value both when given internally and hypodermically in such severe maladies as Asiatic cholera and many other ailments. A large amount of literature might be gathered concerning its value, but I need only quote Alexander, who has used it successfully in the exhaustion of phthisis, and Schilling, who has found its value to be very great in nearly all the severe infectious maladies. While it quiets nervous excitement it seems at the same time to support the circulatory and nervous systems. In advanced typhoid fever I have found it very valuable. The doses I have employed have been fifteen to thirty minims of a 1-to-15 olive oil solution of the drug given hypodermically, and my resident physicians having seen its beneficial results have used it without my orders in a number of urgent cases when I could not be consulted, so effective have they found its action to be.

Our knowledge as to pathology continues to advance not only in respect to new diseases, but far more important in its relation to states which have been thought heretofore to be thoroughly understood. These advances are not alone of scientific interest, for they open up new possibilities as to treatment and explain symptoms hitherto unrecognized or

misunderstood. A few years since the majority of medical men considered that the last new thing had been said about burns and their treatment, or at least that the pathological results of burns were well understood. More recent studies have, however, revealed the fact that there is much to be considered in connection with burn cases over and above the local condition produced by the heat, the more deeply seated secondary lesions and the shock from which the patient suffers. It has been found that a toxemia develops which is an important factor in destroying the patient's life, and that it is our duty to combat this condition quite as much as it is to combat the local damage.

Time does not suffice in which to go over the whole experimental proof of these facts, and it is only necessary to quote some recent studies of Tomasoli, who injured dogs and rabbits by burning, and then studied the effects of hypodermoclysis in aiding them in the elimination of toxins and the survival of shock. All the test animals which did not receive the saline solution in the manner named died within forty-eight hours of the injury, and Tomasoli found that blood serum taken from these animals, being injected into a healthy dog, that animal will die. If, on the other hand, similar animals receive saline injections they nearly always recover. Thus out of ten animals which were burnt and injected only two died, and these apparently from the direct injury rather than from toxemia; and serum taken from the injected dogs when injected into healthy dogs did not produce death as did that from the non-injected animals. Putting these facts to practical use Tomasoli employed similar injections in cases of severe burns in human beings, using 500 to 1000 cubic centimeters of saline solution, and obtained good results therefrom. Whatever may be the ultimate decision in regard to these studies, they open up for us an interesting line in practical research and promise of an additional means of treating a serious medico-surgical condition.

Let me urge upon those whom I have the honor to address one fact in regard to therapeutics which it is well for practitioners to remember when confronted with conditions which seem baffling: namely, that while much of the therapeutics of fifty years ago was crude and not in accord with modern views as to disease processes, much of it was sound. We are so put to it to cure our patients, and so con-

stantly brought face to face with the fact that they are but mortals like ourselves, that we are apt to be off with the old love and on with the new. These facts were recently brought to my attention very forcibly by the following episode: A patient suffering from chronic renal disease with considerable anasarca, marked uremic amblyopia, and the passage of a very scanty amount of urine heavily loaded with albumen and containing very little urea in the twenty-four hours, was given several of the newer diuretics without any material effect. It then occurred to me to employ the old-fashioned prescription of an ounce of juniper berries in a pint of boiling water, to which was added an ounce of potassium bitartrate. The total amount was taken, when cooled, in wineglassful doses, with the result that in a few days the urine increased to a point beyond the ordinary in quantity, the anasarca began to disappear, the vision greatly improved, and the patient passed the normal daily amount of urea. If this remedy had been new it would have been considered quite startling in its effects and widely used when other cases fared as well under it, yet I venture to say that the use of other old remedies which we have discarded at least in part would be fraught with equally good results when newer drugs fail.

While the discovery of the anesthetic properties of ether and chloroform has been followed by the introduction of other agents capable of producing general anesthesia, it is an undeniable fact that our knowledge concerning drugs capable of producing this action, both in regard to the action of old ones and the introduction of new ones, has been disappointingly scanty. Beyond the studies which have been made of the influence of ordinary anesthetic agents upon the respiration and circulation, we know little more to-day as to the method in which anesthesia is actually produced than did our predecessors fifty years ago; and no one has yet succeeded in inventing a substance which has any prospect of supplanting the common anesthetics, which we all recognize have certain distinct disadvantages. In the absence of newer anesthetics it is well for us to continually be on the lookout for improved methods of administering the old ones, and while the majority of physicians are content with the crude methods of previous years, there are others of a more investigating turn of mind who have endeavored to devise methods which would remove many of the disadvan-

tages associated with the older procedures. The number of inhalers which have been upon the market for the use of ether and chloroform is exceedingly numerous, and while their inventors have claimed for them very extraordinary advantages, it remains a fact that the Esmarch inhaler for chloroform and the Allis inhaler for ether are the only ones that have anything like universal recognition, at least in this country; and very many persons are to be found in the profession who freely state that the old-fashioned ether cone and the administration of chloroform dropped upon a napkin still remain our most efficient methods of using these two drugs.

Within the last few years a number of physicians have employed the simultaneous administration of anesthetic vapor and oxygen gas and have found that this combination, particularly when ether is given, tends to prevent vomiting both during and after the operation, that cyanosis rarely occurs, and that the general progress of the case through the influence of the anesthetic is better than under the older methods. For the purpose of this double administration various forms of apparatus have been devised. In several of them the patient is provided with anesthetic vapor and pure oxygen gas alone. In others, and these are rarely met with, he is allowed to have some atmospheric air. In nearly all of the apparatus that we have seen the oxygen gas bubbles up through the ether or chloroform, which has been placed in a wash-bottle, and passes over to the patient's lungs, loaded with the vapor of the anesthetic. There are without doubt certain grave objections to this procedure, for the quantity of oxygen provided to the patient cannot be increased without also increasing the quantity of anesthetic supplied to him; neither can the quantity of anesthetic be increased without increasing the quantity of oxygen, and there are times in every operation in which it is desirable to increase or decrease one of these agents. Then, too, if too much oxygen is given the respiratory center becomes benumbed by superoxygenation of the blood, partial or complete respiratory arrest follows, which is in this instance without any material danger, but with the arrest of respiration it is impossible to give the patient more ether as he does not draw it into his lungs.

By far the best way to use oxygen when ether is given—and I think it always should be employed, if possible—is to allow the oxy-

gen to bubble up in the wash-bottle, thus passing from the cylinder which contains it to the ordinary inhaler which is held over the patient's mouth and nose, the ether being poured upon the inhaler in the quantities which are needed and the oxygen being supplied to the patient by slipping the tube under the edge of the inhaler by the patient's mouth and nose. In this way the patient receives the air which he ought to breathe, the anesthetic vapor, and the additional oxygen, which prevents the disagreeable symptoms which are so frequently met with. In no instance should that apparatus be employed which is now marketed by a number of instrument-makers in which the patient exhales into a large rubber bag which is inflated with each expiration and deflated with each inspiration, the contents of which soon become surcharged with vitiated air, exhaled anesthetic vapor, and impure oxygen. In all such procedures it is wise to let the patient breathe in as nearly a normal manner as possible, and the more simple the apparatus the better it is for the physician and patient. When it comes to administering chloroform by passing oxygen gas through it the objections are still greater. We are learning more and more each day that chloroform when exposed to daylight and the air is capable of undergoing certain degenerative changes, and that the results of these changes are harmful to the patient. Further than this, in chloroform anesthesia it is often necessary to give the patient pure oxygen, but this cannot be done if this double method of passing oxygen gas through the chloroform liquid is carried out. Here, again, we believe that the chloroform vapor and oxygen gas should be kept separate and administered simultaneously or apart as the necessities of the case demand.

The writer desires to protest very emphatically against a habit which seems to be prevalent among young hospital internes, namely, of providing themselves with mouth-gags and tongue-forceps whenever they are about to anesthetize a patient. The writer has seen innumerable cases put under the influence of anesthetics and has made a study of these drugs for years. During that time he has never seen an instance in which it has been necessary to force the patient's jaws apart and keep them so by means of a mouth-gag, except, of course, in cases of operations about the mouth; nor has he seen any instance in which it seemed to him justifiable to pierce the tongue of the patient by means of that

form of tongue-forceps which is provided with one flat blade and one blade armed with two sharp teeth, which pass all the way through this organ, thereby puncturing and bruising it.

The proper manipulation of the head and jaw and neck in the presence of anesthetic accidents in the vast majority of cases is sufficient, and in some instances the forcing open of the jaws and the holding them open by means of the mouth-gag has seemed to aid in the obstruction to breathing by causing the relaxed tongue to fall back into the posterior portion of the mouth, just as it does in a person who is sleeping heavily with the mouth open. The writer mentioned these facts at a recent meeting of the Section on Surgery of the College of Physicians of Philadelphia, and several surgeons who spoke after him agreed that there was rarely, if ever, except in mouth operations, any necessity for the use of these two instruments. They also stated that they had endeavored to find out, without success, who was responsible for teaching medical students their use during anesthesia, as they themselves never employed them nor directed their assistants so to do.

There is no doubt that the mouth-gag and the tongue-forceps are gravely abused, and even if they do no harm during anesthesia, it certainly is unnecessary to produce the after-suffering and discomfort in the mouth which the tongue-forceps often produce.

Finally, the writer desires to express his belief that it is a vital mistake for surgeons to urge upon their assistants the necessity of hurry in producing anesthesia. No physician would think of giving such an enormous dose of chloral that his patient would pass from a condition of wakefulness to deep sleep in the course of two or three minutes. Why should we employ such powerful and rapid-acting drugs as ether and chloroform in such concentrated vapor as to almost instantly produce surgical anesthesia? If the anesthetics are given gently and gradually until the nervous system, both centrally and peripherally, is benumbed, and then pushed as hard as seems wise, disagreeable interruptions of the operation because of threatened accidents, and accidents themselves, will be avoided; for the patient will not struggle and strain his heart and respiratory system at the beginning of the operation, and the general nervous system will not only be saved a large amount of nervous exhaustion, but be protected from shock. Those persons who

have suffered from nightmare are well acquainted with the horrible nervous condition in which they find themselves on awaking, and in many instances the early stages of anesthesia, particularly to a timid woman, are like those of a dreadful nightmare. In one instance a woman who took ether told the writer that she had a delusion that some one was choking her to death, and in this delusion she was not very far wrong, as the writer saw the anesthetist jam the ether cone over her face and hold it there despite her violent struggles, which produced deep cyanosis.

The old saying, "Familiarity breeds contempt," is particularly applicable to the use of anesthetics. Surgeons are so apt to administer these drugs day after day and to be content with the recovery of the patient from the anesthetic on the operating table, or shortly after leaving it, that they entirely overlook these evidences of grave nervous shock which the physician or neurologist frequently meets with after patients have been discharged by the surgeons as entirely well, so far as the operative procedure is concerned. There is reason to believe that with our advancing ideas in regard to the minute anatomy of the nervous system and our studies of the dendrites, at some time in the near future we will understand more clearly the minute physiological action of anesthetic drugs, and then it will be easier for the surgeon to appreciate the grave functional change taking place in the nervous system when they are administered.

In conclusion the writer desires to call attention to a fact already alluded to by him a number of times, and which was first called attention to by his colleague Dr. Martin and himself some ten years ago, namely, that the proper position for the head, when the patient is deeply anesthetized and it is desired to get a clear passageway for the air into the lungs, is in extension and somewhat thrown forward, instead of being extended and dropped backward from the end of the table. Extension and projection forward and backward both pull the epiglottis away from the glottic opening, but in the latter posture the soft palate is strapped over the dorsum of the tongue and the patient is forced to breathe through his nose, which is often partially or entirely occluded by mucus, by hypertrophies, or by polyps; whereas, if the head is extended and projected forward the patient can readily breathe through both the mouth and nasal chambers.

*SOME PRACTICAL POINTS IN THE TREATMENT OF LATE CUTANEOUS SYPHILIS.\**

BY M. B. HARTZELL, M.D.,  
Instructor in Dermatology, University of Pennsylvania.

It is not without considerable hesitation that I bring before this Society anything upon so trite a subject as the treatment of syphilis, a subject which has been so often and so exhaustively discussed that it may well be doubted if there be anything new left to be said. And it is not my purpose to present anything novel in the way of treatment; I have no new or wonderful drug, "made in Germany," warranted to accomplish the complete and lasting rejuvenation of the syphilitic, the virtues of which I wish to extol; but I desire to emphasize anew a few practical points in the treatment of some of the late manifestations of syphilis upon the skin, which my own experience has taught me to regard as useful.

The first point of which I shall speak is the effective dose of the iodides, especially the iodide of potassium, in the late eruptions of syphilis. As laid down in most text-books of therapeutics, the dose of potassium iodide is ten grains, repeated several times a day; a dose of less than five grains is almost never prescribed in syphilis, and fifteen- to twenty-grain doses are extremely common. Now it is a fact, easily verified by any one who will take the trouble to experiment in this direction, that much smaller doses than these are often quite effective, and promptly so, in causing the disappearance of the lesions of syphilis upon the skin. So small a dose as a single grain, given three or four times a day, will in many cases remove the tubercular syphilide quite as rapidly as the larger amounts commonly recommended; and that, too, without the derangement of the stomach which in a not inconsiderable proportion of cases attends the use of this drug in the ordinary doses. As illustrating the efficacy of these small doses I may be allowed to refer very briefly to a few cases:

Mary N., thirty-four years old; half-dollar-sized patch of syphilitic tubercles on the forehead; a much larger patch of like lesions in the left scapular region, extending from the top of the shoulder to the lower angle of the scapula; duration seven months. Potassium iodide was prescribed in two-grain doses three times a day, the small dose being employed for the purpose of preserving the case

\*Read before the Philadelphia County Medical Society, March 23, 1898.

for class demonstration a week later. As often happens with ambulant patients, she did not return at the appointed time, but two weeks later; the improvement was then so marked that the case was no longer useful for clinical purposes.

George E.; tubercular syphilide of the palm; duration twelve months. For the same reason as in the preceding case iodide of potassium was given in one-grain doses three times daily. At the end of three weeks the lesions had in large part disappeared.

George S.; tubercular syphilide of the forehead; several months' duration; iodide of potassium in one-grain doses; marked improvement at the end of two weeks.

In each one of these cases the improvement was as rapid and decided as in any in which the usual five- and ten-grain doses had been employed. I would not be understood as advocating these small doses in all cases, since I am well aware that much larger quantities are often necessary to produce the desired result. In the beginning of treatment, however, it is well to try them, since, as Mr. Hutchinson long ago pointed out, it is in the early stages of treatment that these small doses often seem to do quite as well as much larger ones.

In rare cases it will happen that even small quantities of the iodides produce so much disturbance of the stomach that their administration in any effective dose is impossible. In these the drug may be given by enema with quite as good therapeutic results as when given in the usual way. This method of administration, although advised in some text-books, is not, according to my observation, employed as frequently as it deserves to be. The following case well illustrates the efficacy of this method of giving the drug:

Mrs. W. L., who had a number of times been under my care for various manifestations of syphilis, upon one occasion presented herself for the treatment of a gumma upon the forehead. Her stomach had become so intolerant of the iodides that it was no longer possible to give them in effective doses by the mouth, and mercurials seemed to have but little effect besides being also badly borne. Fifteen grains of potassium iodide was given by the rectum twice a day for some weeks with perfectly satisfactory results; and three years later, when there was a marked paralysis of the left half of the tongue, the same method of treatment was pursued with equally favorable effect.

The therapeutic effect of the iodides is

usually so promptly and decidedly manifested in the various forms of tertiary syphilis that we are apt to overlook the fact that in some cases, happily rare, no result follows their use in any dose. It is particularly important to remember this when endeavoring, in doubtful cases, to make a diagnosis *ex juvantibus*. In a few instances I have known the diagnosis of syphilis, at first correctly made from the clinical features presented by the cutaneous lesions, rejected because of the failure of treatment by the iodides. The following case is illustrative of this point:

J. W., a young Polish Jewess, had suffered for a considerable period from an ulcerative affection of the nose which had destroyed a large part of that organ. The diagnosis of syphilis having been made, iodide of potassium was given in large and increasing doses until six drachms a day was being given. This treatment having failed absolutely to produce any remedial effect, the patient's attendant began to regard the disease as probably a scrofuloderma. Before giving up the diagnosis of syphilis completely, however, it was suggested that mercurial inunctions be tried; and within six weeks the nose was entirely healed.

In concluding, I wish briefly to call attention to the advantages possessed by mercurial plaster as a local application in the treatment of ulcerating, syphilitic lesions. It is much more convenient and cleanly than the various mercurial ointments usually prescribed; and when freshly prepared it may be made to adhere to the affected part without the use of any other dressing.

---

*A SUCCESSFUL MODE OF ADMINISTERING  
BEECHWOOD CREOSOTE IN  
PULMONARY TUBERCULOSIS  
AND OTHER DISEASES.*

---

BY CHARLES WILSON INGRAHAM, M.D.,  
Binghamton, N. Y.

---

Beechwood creosote is a remedy of wide clinical usefulness, and administered with discretion, in a proper manner, it will be found, contrary to the general impression, uniformly reliable in its effects. In my opinion nine-tenths of the disastrous results which have been attributed to the effects of creosote are the result of administering the drug in a manner incompatible with its digestion and assimilation, or to the use of an inferior quality of the remedy, and in many instances both these factors enter into the case.

While creosote is of undoubted value in

the prevention, relief, and cure of a wide range of organic and functional diseases, both acute and chronic in character, it has attained its greatest usefulness in the treatment of tubercular diseases, particularly tuberculosis of the lungs.

Properly administered in pulmonary tuberculosis, beechwood creosote fulfils in a thorough and reliable manner a diversity of medicinal effects which, directly and indirectly, exercise a powerful control over the disease.

By the use of creosote in pulmonary diseases, in the manner which I shall describe in this article, it has, in my experience, shown itself to exercise a very beneficial influence over the functions of digestion and assimilation, and certainly its systematic use protects the invalid against recurring attacks of indigestion and certain forms of gastritis peculiar to tubercular patients. Further than this, I have found that creosote, by a direct germicidal effect, also protects pulmonary invalids against secondary tubercular invasion of the intestinal tract.

In the treatment of typhoid fever it has been shown that creosote, or its derivative, guaiacol, properly administered, eliminates much of the danger of the typical ulcerative processes in the intestines characteristic of typhoid disease, limiting the superficial extent of these ulcers, and in a similar manner lessening the structural damage, thus reducing the danger of intestinal hemorrhage, intestinal perforation, and peritonitis, the most dangerous complications to which the typhoid invalid is exposed. In a like manner creosote preserves the vitality and maintains the structural integrity of the intestinal mucous membrane, protecting the phthisical invalid against secondary tubercular invasion of the intestines. As will be appreciated, by protecting against secondary tubercular invasion of the intestines creosote eliminates from pulmonary tuberculosis one of the most dangerous secondary complications, for after tubercular disease has gained a footing in the intestines, the prognosis immediately becomes very grave.

It would appear doubtful what the exact views of a certain percentage of practitioners are as to just what therapeutic action is expected of beechwood creosote administered in pulmonary tuberculosis. At one time it was apparently expected that a sufficient amount of creosote could be introduced into the general circulation to secure and maintain a germicidal condition of the tissues and

fluids of the body, which in turn would communicate a destructive effect to the tubercle bacilli, destroying these germs *en masse*. But this theory, which for a time prevailed in the face of scientific impossibilities, and to which much of the present unpopularity of creosote is due, has ceased to exist, and creosote is now attaining its just status as a therapeutic agent.

All will admit that creosote has been notoriously abused. Patients treated with the drug after the manner referred to were abused. Diseases treated in the manner referred to were abused.

While the theory existed that it was possible to saturate the blood, the tissues and the fluids of the body with creosote, and secure as a result a germicidal condition of the same, there was a strife among certain members of the profession, particularly in Europe, to determine who should succeed in administering the largest daily quantities of creosote; and so absorbed were practitioners in this mathematical contest that apparently the physiological effect of the drug, administered in these enormous doses, became for the time being a secondary consideration. But happily this state of affairs has ceased to exist, and at the present time no physician thinks of attempting to administer 150 minims of creosote daily, and all understand perfectly that, administered in these enormous doses, the effects are in no way superior to moderate doses, and at the same time the large doses are distinctly harmful. It is the effects of creosote, both direct and indirect, which now receive the earnest attention of the profession, and creosote under these conditions must become recognized in its proper light, and will soon reach the sphere of general usefulness to which it belongs.

No longer does any physician entertain the idea, either in relation to creosote or any other drug, that it is possible to transmit to the general system direct germicidal power, and secure as a result a direct germicidal effect upon the tubercle bacilli sufficient to secure the elimination of these germs from the body. Nature has shown the true manner of eliminating tubercle bacilli from the body, and permanently healing the lesions, and further, what is equally important, protecting the general system against subsequent attacks.

It is through the medium of general constitutional vitality that tubercular disease is permanently cured. General vitality is not restored and maintained through the agency

of powerful germicides. It is the direct product of normal constitutional nutrition and normal tissue oxidation.

Beechwood creosote, by its power to prevent functional disturbances of the organs of digestion and assimilation, by favoring normal action of these organs, by securing and maintaining a healthy appetite, and through these several effects securing uninterrupted digestion and assimilation of nourishment from day to day, brings about a state of general constitutional nutrition, and its product, constitutional vitality.

As to the most effective and least objectionable manner of administering creosote opinions differ, but from my personal experience with various preparations of the drug I believe that the mode of administering creosote that I herewith describe will be found to be a most generally useful and widely applicable method of introducing this remedy into the general system.

There are numerous preparations of creosote, which, as a result of chemical refinement and union with other chemical products, have relieved the drug of its irritating and poisonous character to a greater or less extent, and rendered its use comparatively simple. While these refined products of creosote and chemical compounds containing creosote are of undoubted value, their expense is a factor which interferes with their popular use, and I believe their efficacy does not excel, if indeed it equals, the benefits which may be secured from the crude drug.

I have stated that it is of first importance to secure a superior quality of the drug, and this done, I give my patient one ounce of beechwood creosote and an empty twelve-ounce bottle, and after cautioning him that the remedy is a poison, I direct his attention to the following label upon the creosote bottle: "Put four drops of the creosote in the empty twelve-ounce bottle, and take the same according to the directions to be found on that bottle. The second day put five drops of the creosote in the twelve-ounce bottle, the third day put in six drops, and thereafter continue to increase the amount of creosote one drop each day, until fifteen drops are taken daily. After the dose has reached fifteen drops per day, increase at the rate of one drop every second day, until twenty drops per day are taken. After having reached a daily dosage of twenty drops, increase the dose at the rate of one drop every third day, until twenty-five drops per

day are taken. Do not increase beyond twenty-five drops per day without special instructions."

On the empty twelve-ounce bottle I place the following directions: "After putting in the correct number of drops of creosote, according to the directions contained on the creosote bottle, fill this bottle with fresh water each morning, and take the entire contents of the bottle, during the day, in equally divided doses at regular intervals, making at least six or eight doses daily. Shake the bottle thoroughly each time, immediately before using, and be sure that the creosote is thoroughly distributed through the water."

By beginning with minute doses of four drops per day—which, taken in eight doses, makes half a drop of creosote per dose—and by increasing the daily dosage from this minimum amount in the ratio described, there seldom occurs the slightest trouble from its use, and on the contrary many patients declare that the creosote creates an effect very agreeable.

Many have found that creosote taken in this way relieves the throat of irritation directly, promotes expectoration, and relieves a large proportion of the irritating cough characteristic of tuberculosis.

I first described this mode of administering creosote in the *Medical News* of April 13, 1895, and, as in that article, I recommend that Merck's creosote be used, as it is in my opinion the most uniformly reliable of all creosote products. It is advisable to purchase the creosote in original sealed bottles.

I have, by this method, increased the dose to thirty-five minims daily without the slightest objectionable effects, though in my opinion twenty-five minims per day will produce all the therapeutic effects of larger doses.

Much of the benefits of this mode of administering creosote must be attributed to the manner in which it is introduced into the stomach, though the method of preparing a fresh solution each morning, which protects against stale solutions, and assures the highest degree of potency, no doubt has much to do with the uniformly good results.

In case the creosote fails to stimulate the appetite as desired, it is advisable to add to the creosote water either of the following vegetable bitters: One ounce tincture gentian, tincture columbo, tincture quassia, or a small amount of nux vomica may be added when desirable. Also pepsin, pancreatin and other digestive agents may be added.

I am sure that after this method of admin-

istering creosote has been given a careful test, creosote pills, creosote emulsions and alcoholic solutions of creosote will seldom be prescribed.

*THE STATISTICAL EVIDENCE IN FAVOR  
OF THE EXCISION OF CHANCRE AS A  
MEANS OF PREVENTING SYPHILIS  
OR LESSENING ITS SEVERITY.*

BY FRANCIS D. PATTERSON, M.D.,

Assistant Surgeon in the Genito-Urinary Dispensaries of the  
University and Polyclinic Hospitals.

Our knowledge of the origin of syphilis is wrapped in obscurity and probably will never be definitely settled. Certain it is, however, that it can be traced back about as far as the history of man; an old Chinese medical manuscript dated 2000 years before Christ contains an accurate description of it.\* Nearly all of the earlier Latin, Greek and Arabian writers on medicine make reference to it. In 1492 syphilis swept through Europe as an epidemic, and this may well be termed the "period of confusion," for the reason that they then believed that all venereal lesions were due to one and the same virus. This was the prevailing belief until the year 1852. In this year Bassereau,† to whom should be given the credit for the original suggestion, and Ricord‡ declared that syphilis and chancre were separate and distinct conditions in nature as well as in origin. Thus the "Dualistic" School came into being. To-day every one recognizes the distinctive differences between chancre and chancroid.

For many years the etiology of syphilis has been the subject of exhaustive bacteriological and clinical research. The discovery of the specific micro-organism has been "announced" more than once, but as yet in no case has syphilis followed the attempted inoculation of a healthy person with these so-called specific germs taken from a culture on artificial media. Though the bacteriological proof of the germ origin of syphilis is still wanting, this disease clinically presents an almost perfect picture of this origin. The chancre is the result of this invasion of germs, and so is only found at the point of inoculation. Its characteristic sclerosis is a proof of the attempt of Nature to prevent as far as possible the further entrance of the

germs into the system. Those germs that do enter are carried on to the nearest lymphatic glands, which undergo hypertrophy as the result of their presence.

The malaise, muscular pains and fever which precede the appearance of the secondary phenomenon have been thought to be the result of a toxemia, the toxin being absorbed from the germs which are yet localized at the chancre. The secondary lesions of the skin and mucous membranes are the direct result of the local deposit of the specific virus. Its transmissibility to offspring is but another evidence of its bacterial origin. The acquired, Prozetas and Colles immunities are all evidences of a similar origin. Still further evidence is seen in the fact that the disease presents different forms or types of severity, varying in the number and virulence of the infecting micro-organisms. Thus it may be so benign that the secondary symptoms will never be noted by the patient and he will be unaware of his condition until the development of the tertiary symptoms, which are in these cases very mild. Again, on the other hand, the disease may run a malignant course from the first; the secondary symptoms being very severe, the tertiary coming on in a few months, and often causing the death of the patient. The clinical characteristics of the initial lesion are briefly its induration, its incubation, and its course. This induration is the result of a round-cell infiltration into the connective tissue and the adventitia of the blood-vessels around the infected area. This represents the attempt of Nature to prevent the spread of the germs into the system.

The extent of the initial lesion often bears a direct ratio to the severity of the secondary symptoms, as clinical experience clearly proves. So recognizing that syphilis is probably due to a specific micro-organism, and that infection with this organism produces the chancre, it would seem that the chancre bears the same relation to syphilis that the poisoned wound does to cellulitis. The prompt removal of any localized area of infection is a sound surgical principle. So it would seem that if we admit the bacteriological cause of syphilis the removal of this area of infection would be the proper treatment.

The first excision of a chancre was performed by Corbis in 1693 in the Hospital of Lille in France.\* Since then this operation has been performed many times with

\* Otis: Practical Clinical Lessons in Syphilis, etc., U. S., 1883, p. 19.

† *Traité des Affections de la peau Symptomatique de la Syphilis*, Paris, 1852.

\* Quoted from Leloir, Transactions of the Tenth International Congress, Berlin, 1890, B. iv, p. 68.

varying success, as we see from the following statistics:

Reporter.	Total number cases.	Successful.	Unsuccessful.	Not known.
Ehlers.....	584	137	447	..
Crivelli.....	454	102	339	13
Munn.....	1	1	..	..
McGuire.....	2	..	2	..
Mauriac.....	1	..	1	..
Humbert.....	12	1	11	..
Bumstead.....	15	..	15	..
Zeissl, Mauriac, and Neuman.....	17	..	17	..
King.....	7	1	6	..
Leloir.....	33	10	22	1
Chadzynski.....	30	7	16	7
Watraszen- ski.....	15	1	14	..
Auspitz.....	23	14	9	..
Hueter.....	7	2	5	..
Sigmund.....	39	35	4	..
Langenbeck.....	2	1	1	..
Kuszlinski.....	1	1	..	..
Köllicker.....	8	3	5	..
Rydygier.....	3	3	..	..
Tollnauer.....	19	8	11	..
Pich.....	1	1	..	..

Thus out of 1274 cases of excision, 925 were followed by secondaries; in 328 cases no secondaries resulted; in 21 cases the result was not ascertained.

These statistics show that excision does not abort the disease in every case, but clinical notes on many of the above cases prove that it does markedly lessen the severity of the secondary symptoms; in fact, in many of them the only subsequent symptoms were those of general adenopathy and slight cutaneous eruption.

In conclusion I would say:

1. That syphilis is a bacterial disease.
2. That the chancre occurs at the point of infection.
3. The induration of the chancre is the attempt of Nature to limit the disease.
4. That the chancre is an infecting wound and a man has syphilis because he has a chancre, not that he has a chancre because he has syphilis.
5. That the chancre should be treated as any other area of local infection—*i.e.*, by its removal.

#### KRYOFINE.

BY JOHN H. CURTIS, M.D.,

Professor of Therapeutics and Clinical Instructor in Medicine,  
College of Physicians and Surgeons; Attending Physi-  
cian Lake Geneva Sanitarium, Chicago, Ill., etc.

Accepting the theory that infectious diseases are combated by an antitoxin developed in the blood of the infected patient, the elevation of bodily temperature in infectious diseases is undoubtedly one of the elements of recovery, for it is part of the means of the development of the antitoxin which is to neutralize the infection; hence reducing the temperature is not always the wisest therapeutic procedure. Nevertheless the temperature may rise to the point where it is of itself dangerous to life, or the cause of a protracted convalescence due to tissue changes produced. Undoubtedly the best and safest means of subjugating this hyperpyrexia is by means of water, as tubbing, the wet pack, or the sponge bath. One of these is always attainable in hospital practise or where intelligent nursing can be procured. The general practitioner, however, is constantly called upon to treat cases where this desirable condition of affairs is out of the question and yet in which he feels the necessity of controlling the temperature. He is then brought face to face with the question of a choice of remedies, and it is in this connection that I wish to call attention to one of the newer synthetical compounds, a coal-tar derivative—kryofine. I am not desirous of stating that this is the best remedy in all cases of fever, as, for instance, where there is great arterial excitement and tension, and where aconite or veratrum viride is unquestionably the best remedy.

This remedy was discovered by Dr. Bischler and brought prominently to the attention of the profession by the publication of the clinical experiences of Professor Eichhorst and Dr. Bresler. It is produced by heating p-phenetidin with methoxyacetic acid to 248°–266° F.; it crystallizes from water in needles with a melting point at 208.4°–210° F. It occurs as white, odorless and tasteless crystals; soluble in 600 parts of cold, 52 parts of

boiling, water; also in alcohol, ether, chloroform, glycerin, and fixed oils. Upon boiling with alcoholic caustic potash solution the greater part is saponified, and with hydrochloric acid it is saponified with less difficulty than most coal-tar derivatives. Under its influence the pulse becomes fuller and stronger, with a disappearance of dicotism. Abnormal temperature is reduced surely and promptly, in a marked degree, and extending over several hours of time, without rigor or depression, and rarely attended by diaphoresis. Blood-pressure is increased, and according to the observations of Bach the increase of blood-pressure is in harmony with the falling temperature. In the few cases in which there was no reduction of temperature there was an absence of increased blood-pressure. Respiration is not affected. It is eliminated in about six hours, by the kidneys principally, although it does not affect diuresis, and may be found in the urine fifteen minutes after its ingestion. This demonstrates its rapid absorption. The rapid and more or less complete saponification by the stomach and intestinal juices, is probably the secret of its power and the reason for its prompt action. It controls neuralgic pain in a marked and sometimes almost magical manner, and in some persons produces a tendency to sleep. I have been using it for about a year and have the records of a large number of cases, a few of the typical ones of which are appended. Perhaps its chief value will be as an analgesic, because of the greater number of cases requiring relief from pain. For the average adult eight grains seems to be the dose giving best results. In only one case (Case IV) were any objectionable collateral symptoms observed. This was in a lobar pneumonia with very high temperature, and ten grains every six hours produced some cyanosis of lips and finger-tips, which, however, disappeared in a few hours.

CASE I.—Acute follicular tonsillitis. Miss C., aged six; for twenty-four hours very restless, with headache, backache, hot dry skin, pain upon deglutition. Pulse 120; temperature 103°. Examination of throat showed follicular tonsillitis. Had had several attacks during past three years. Gave three grains kryofine every four hours, with an antiseptic and astringent throat wash. Next morning the temperature was normal, and headache and backache gone, with much improvement in condition of throat. She made an uneventful recovery. This is one of eight or nine similar cases.

*Influenza.*—During the epidemic of the past winter I have used kryofine in a large number of cases. The uniformity of clinical symptoms renders extended reports of individual cases unnecessary.

CASE II.—La grippe (bronchial type). I was called to Mrs. M., aged twenty-eight, at 10 A.M., and found her suffering with intense backache, pain and soreness in the muscles of the limbs, especially the extensor groups, headache, a painful tension in the eyes and forehead, considerable faucial congestion, and a severe bronchial catarrh. Intense weakness; some nausea; anorexia. Pulse 115; temperature 103.2°. Gave eight grains of kryofine at 10 A.M. and 3 P.M.; also a stimulating expectorant. At my next visit, 7 P.M., temperature was 100°, pulse 90. Headache and muscular pains disappeared after first dose. Skin was moist, but there was not excessive diaphoresis. Patient was given these same doses at the same hours the following two days, and the temperature did not go above 99½°. There was continued amelioration of all the subjective symptoms. The intense weakness continued for about a week and yielded only after the appetite and general vitality had been stimulated by strychnine.

CASE III.—La grippe (nervous type). Mr. C., aged thirty-eight; headache and backache, with general muscular soreness. Had chronic bronchitis, which was somewhat aggravated; occasional shooting pain through the head, starting from the ears and temporal regions; no appetite; extremely nervous and irritable; melancholy most of the time; insomnia, sleeping but two or three hours per night for the past three nights. Pulse 95; temperature 101°. Five grains kryofine every four hours during the day and ten grains at bedtime relieved the pain and muscle soreness and quieted much of the nervous excitability. Fifteen grains sodium bromide was given with the ten-grain dose at bedtime, and the patient slept twelve hours the first night. Temperature next day did not go above 99°. Stimulated appetite with bitters, and the patient recovered normal condition in a few days.

I have noticed the tendency to sleep in several cases after a ten-grain dose, even when given without the bromide.

In typhoid fever my experience with kryofine has been limited, cold having been the antipyretic agent usually employed. In the cases in which I have used it, however, I have noted that the temperature was reduced

from  $2\frac{1}{2}^{\circ}$  to  $3\frac{1}{2}^{\circ}$ , without producing any unpleasant symptoms whatever, such as chill, depression, cyanosis, etc. I have noticed that the administration of a dose of six to eight grains about an hour before the time of the highest temperature prevents in a large measure the temperature from going beyond the danger point.

In pneumonia the remedy has been used in several severe cases, with a reduction of temperature of from two to three degrees. In one case only (Case IV) was there any collateral effects. I am of the opinion, however, that, except in occasional cases, the use of agents that reduce temperature by lessening the oxygen-carrying capacity of the blood is not good therapeutics in lobar pneumonia.

CASE IV.—Pneumonia. Male, aged thirty-four. Upon the fourth day of disease temperature was  $104^{\circ}$  to  $104\frac{1}{2}^{\circ}$ . Ten grains kryofine, repeated in four hours, reduced the temperature to  $102^{\circ}$ . There was some cyanosis of the lips and fingers, which disappeared in a few hours upon increasing his doses of strychnine. Crisis occurred next day, and further antipyretics were not required. Recovery uneventful.

CASE V.—Mrs. G., aged twenty-seven, nervous temperament, was confined November 21, 1897. Easy labor under aseptic precautions. On the ninth day she expected to get up. Upon my advising a few more days in bed she was greatly disappointed and imagined there was something wrong of which I had not informed her. She cried and worried over it, and next morning her temperature was  $103^{\circ}$ , pulse 118. Careful examination eliminated septic causes. Eight grains kryofine was given, and in the afternoon temperature was normal and nervous system calm.

For the relief of pain kryofine acts very rapidly and surely, the relief often occurring within fifteen minutes. The class of cases in which it acts best are of neuralgic type. Of a record of a large number of cases I append four. In no case have I been disappointed in obtaining relief. Of course pain will return unless the cause be sought for and removed.

CASE VI.—Mrs. H., aged thirty-eight, for twenty years has had frequent attacks of pain over left eye, which she attributes to a fall down stairs in which she struck her forehead on the edge of an iron pan. There is a slight depression in the forehead just to the left of median line. The attacks of pain usually

last three days and compel cessation of all household duties. At the beginning of the last three attacks she has taken ten grains of kryofine and repeated the dose once or twice each day, with almost complete relief of pain.

CASE VII.—Miss W., aged twenty-four; telephone operator. For past three months she has suffered almost continuously with severe lancinating pains in right side of head. For past six weeks she has been confined to bed. She has tried numerous remedies and several doctors with scarcely any relief. The last physician finally gave morphine, each dose of which relieved her for an hour or two. I was called the evening of February 10, 1898, and found her complaining of the pain mentioned. Had not slept for over an hour at a time for several weeks. Scalp was excessively tender, especially on the right side. Photophobia; there was quite a severe acute iritis in the right eye. No history or suspicion of syphilis. Pulse 90; temperature  $99^{\circ}$ . Tongue coated; bowels constipated; poor appetite; rheumatic diathesis suspected. Gave eight grains of kryofine and repeated in four hours. Next morning found patient had slept all night for first time in weeks. Entirely free from pain, but scalp excessively tender. Prescribed a laxative, seven grains soda salicylate every four hours, and atropine and hot applications for the eye. Also directed patient to take kryofine upon the return of pain. This was done upon several occasions for two or three days, and pain has not been severe since the first dose, and has not returned after the third day. Recovery complete.

CASE VIII.—Sciatica. Male, aged twenty-eight; of rheumatic tendencies. Since January 3 he has suffered severely with sciatica of left side. Eight grains kryofine every six hours gave almost complete relief from pain. Patient is taking iodide of potassium, salicylate of sodium and colchicum three times daily and is rapidly recovering.

CASE IX.—Mrs. F., aged thirty-four, six years ago had a severe attack of cerebrospinal meningitis, leaving her with a divergent strabismus. For the past five years she has had occasional attacks of severe pain in back of head and neck, lasting two or three weeks. During her last attack, which began February 1, 1898, I gave eight grains kryofine morning and night, with complete relief of pain. Put her upon syrup of iodide of iron three times daily. There has been no return of pain as yet.

CASE X.—Neuralgia. Mr. B., aged fifty,

in January, 1898, had la grippe lasting about a week. Since recovery he has had frequent, almost daily, attacks of sharp pain in back part of head, lasting usually about six hours. On March 1 I prescribed ten grains of kryofine to be taken at beginning of these attacks. There was complete relief from the first, and no more attacks after the second day.

From the foregoing cases and a review of many others I conclude that kryofine is: First, a prompt and safe antipyretic, unusually free from unpleasant collateral effects; and second, an analgesic of great power and rapidity of action in all cases of neurotic character.

Kryofine is easy of administration, being tasteless, and is best given in powdered form, dry, upon the tongue. The tablets are not advisable unless first pulverized. Their effects are not so rapid or sure, probably because of the mixture of acacia necessary for their adhesion and compression.

#### COLOTOMY AND COLOSTOMY.

MOSETIG-MOORHOF (*Wien. Med. Presse*, 1898, No. 3) reviews the accepted methods of forming an artificial anus, and describes a modification in technique which he has found useful in certain cases. The classical inguinal operation—that of Littre—he terms “colostomy;” it consists in bringing the descending colon up to the anterior abdominal wall, to which it is stitched, the opening into the lumen being made at once or after an interval, according to circumstances. The disadvantage of this simple operation is that it does not entirely prevent the entry of feces into the distal part of the bowel, where they stagnate and tend to set up inflammatory troubles. To prevent this Madelung introduced true colotomy, in which the gut is cut completely across, the proximal portion brought out of the wound, and the distal closed by sutures and returned to the abdomen. This method is not entirely satisfactory, as the distal end tends to become distended by the accumulation of its own secretion, which may eventually lead to ulceration. König and Sonnenburg obviated this difficulty by leaving the upper extremity of this portion open and attached to the abdominal wall below the artificial anus; by this means the rectum can if desired be irrigated from above.

Another means of preventing feces from getting into the rectum is by the formation

of a spur, first devised by Verneuil, whose original plan has been considerably improved by late surgeons. The disadvantage of both this method and colotomy is that they require a long and freely movable colon and mesocolon; when they are inadvisable or impracticable the author recommends the method he has himself devised. This consists in the ordinary operation of colostomy performed at one sitting, but preceded by partial occlusion of the distal portion of the bowel. A ligature is tied around this, occluding it to about one-half its diameter, and the bulging serous surfaces on either side are sewn together with interrupted stitches. An artificial constriction is thus produced, which prevents the accumulation of feces in the rectum. In attaching the gut to the belly wall the author first sews the serous and muscular coats of the intestine to the parietal peritoneum, and then passes the ordinary sutures through both bowel and abdominal wall. If, however, this would lead to considerable tension, he prefers to attach the intestine to the fascia of the external oblique, leaving the skin free but shutting off the muscular planes from the risk of infection.—*British Medical Journal*, March 12, 1898.

#### CHLORHYDRATE OF EUCAINE IN RHINOLOGY, LARYNGOLOGY, AND OTOTOLOGY.

MARTIN (*Rev. Otol.*, February, 1898) states that eucaine, a derivative of cocaine, should be commonly employed as chlorhydrate. This salt is soluble in 15.6 per cent. water and is not decomposed by boiling, thus differing from chlorhydrate of cocaine and allowing the surgeon to be absolutely sure that a sterile solution is employed. Application of saturated solution to the mucous membrane of the throat and nose produced complete anesthesia in four minutes, lasting for six minutes. It is never followed by cold sweats, fainting or excitation so common after the use of cocaine. It often, however, gives a sensation of heat, or excites cough. It does not cause the mucosa to shrink and is not followed by free bleeding.

Cortaz, in discussing this communication, stated that after the employment of eucaine in some twenty cases he returned to cocaine because its effects lasted longer; moreover, the application of eucaine solution was often painful.

### THE ABUSE OF STRYCHNINE AS A STIMULANT.

The papers which have been published in the medical journals during the last few years emphasizing the value of strychnine as a cardiac and respiratory stimulant have been so numerous that many members of the medical profession are wont to regard it as being one of the best remedies which can be utilized to combat failure of either one of these vital functions. While we are thoroughly in accord with the view that strychnine is a powerful stimulant to these functions, we distinctly disagree with the habit which many practitioners have fallen into of employing this drug day after day for considerable periods of time for the purpose of stimulating the heart. Cases are frequently seen by us in which a physician has administered a dose of strychnine for a day or two with the result that there has been marked improvement in the symptoms. This improvement has then ceased to exist; and on the principle that the patient needed a larger dose a larger quantity has been given, until at the end of several weeks the patient has been taking quantities of this nervous stimulant and irri-

tant which at the beginning would have been quite impossible.

As its use is continued, however, the improvement in the symptoms which first took place fails to be maintained, and finally, notwithstanding any dose that can be given, no relief is obtained from its use. In addition to the primary symptoms there is added a condition of excessive nervous irritability which in some patients is not only disagreeable but actually alarming, at least to the patient who has submitted to it, if not to the physician. Particularly is this true where very large doses of strychnine are administered to patients suffering from severe asthenic maladies, as for example in typhoid fever, tuberculosis, or epidemic influenza. In each and every one of these diseases a few doses of nux vomica or strychnine will frequently produce a noticeable improvement in the pulse and in the apparent condition of the nervous system, because strychnine being a powerful stimulant whips up the flagging nervous centers and causes them for the time being to perform their functions with greater activity. If the strychnine is persisted in, and ascending doses are given for a considerable period of time, in addition to the nervous symptoms which we have mentioned there is frequently developed an irritant fever, and particularly is this the case when strychnine is given in full doses during the later stages of typhoid fever or during convalescence from this disease, when, as is well known, anything which disturbs the nervous centers is very apt to result in a rise of temperature. Physicians are wont to watch the patient taking large doses of strychnine in order that this dose may be cut down as soon as twitching of muscles of the forearms or slight stiffness at the nape of the neck is developed, but in our experience, in asthenic patients, long before these symptoms appear there develops mental disquietude and a condition of what might be called "explosive nervousness," which is most unfortunate. This condition we have already called attention to under the name of "strychnine delirium" in an earlier issue of the GAZETTE.

Only recently we have seen several cases which emphasize these points. One was a patient suffering from typhoid fever who did not seem to take and use alcohol very well, although it was evident that his circulation required some stimulation. Strychnine was given to him in moderately large dose, with the result that for a day or two his circulation was improved, but at the end of that

time the poor circulation returned and the patient began having evening rises of temperature of a considerable degree, which induced the physician in attendance to go back to the pure milk diet which had been previously rigorously enforced. As soon as the strychnine was taken away the fever ceased and it became evident that there was no reason for modifying the patient's diet. In another instance a patient, suffering from the depression of influenza during convalescence, received large ascending doses of tincture of nux vomica and became, as he expressed it, "wild with nervousness." In a third instance a student of medicine suffering from asthenopia was ordered, by a well known ophthalmologist, ascending doses of nux vomica, which he took for a period of three weeks, at the end of which time he was taking thirty drops of the tincture three times a day. When he presented himself for treatment he complained of excessive nervousness, as he expressed it, "fearful thoughts," and suffered continually from a sensation that if he was not in a condition of activity something evil would happen to him. These symptoms were entirely removed by stopping the nux vomica and by directing the patient for a few days to take more than his usual quantity of outdoor exercise.

Strychnine or nux vomica is undoubtedly a remedy possessing great powers of stimulation, but we believe that its use should be limited to those cases in which we desire to call upon the nervous system for a sudden effort, as in meeting a crisis in a case of collapse or syncope. It is the lash of the whip which applied violently to a horse about to become "mired" may sting him into such an excess of activity that he raises himself from the quicksand in which he is sinking. So in medicine strychnine may be regarded as a valuable remedy to meet an emergency, but there is nothing which indicates that its continual use as a nervous or circulatory stimulant is wise, and there is much which indicates that such use of it is unwise.

Whatever influence strychnine may exercise upon the circulation is in reality due to its effect upon the nervous system, as it is not a direct cardiac stimulant of any considerable power.

In the discussion of a paper upon Diphtheria, which recently took place in New York, Dr. Winters asserted that in cases of cardiac disturbance in diphtheria he had found that strychnine was practically useless, and he stated that Dr. Welch, of Philadelphia,

entertained the same views. Personally, we agree with these gentlemen to the extent indicated by the previous remarks, but in sudden cardiac failure we believe that strychnine is the remedy which affords more hope of relief than any other which we can employ, although, as is well known, sudden cardiac failure in the course of diphtheria is one of the most fatal accidents which we have to combat.

*THE VALUE OF HYDRASTIS IN THE  
TREATMENT OF UTERINE HEM-  
ORRHAGE.*

---

Hydrastis has been employed by both regular and irregular practitioners for many years as a remedy for catarrhal conditions of the stomach and intestines, and also for inflammatory conditions of a catarrhal character in the genito-urinary tract of the male rather than of the female. The question whether it exercises any considerable power over the genito-urinary apparatus other than by acting as a tonic to the gastro-intestinal mucous membrane, and thereby improving general nutrition, is one of considerable interest and about which there seems to be a good deal of difference of opinion. As long ago as 1886 an abstract of a paper by Kugelmann appeared in one of the early numbers of the *American Medical Digest* in which he claimed that the use of hydrastis very materially checked the menstrual flow, and it has been suggested that it be employed not only in cases of excessive menstruation, but in those instances of profound anemia where in the opinion of some clinicians moderation or almost complete arrest of the menstrual function is of value as a means of preventing the periodical drain on the system. A few years after Kugelmann's paper had appeared the late Dr. Jackson, of Chicago, reported that he had found this use of hydrastis distinctly valuable, and his evidence may be taken as supporting that of Schatz, of Rostock, who was one of the first to employ hydrastis as a uterine tonic. Dr. W. Reynolds Wilcox has also recorded his experience with the drug in arresting excessive menstruation, and it is worthy of note that Dr. Jacobson considered hydrastis superior to ergot for the purpose named. At most, however, it cannot be expected that the hydrastis will do more than modify the menstrual flow; and Jackson admitted in his paper that by no means in his power, such as tamponing, the use of heat, the use of ergot, or the use of hydrastis,

or of all three together, had he been able to produce artificial suppression of menstruation. That the drug does, however, possess some influence upon menstrual flow and upon hemorrhages from the uterus seems pretty well proven at this time by the gradually accumulating reports which have been placed before us, and while it is by no means a specific, it is one to be considered when the physician comes face to face with a condition which these peculiarities of the remedy will meet.

*THE TREATMENT OF SEROUS EXUDATIONS IN THE PLEURAL CAVITY BY THE SALICYLATE OF SODIUM.*

---

A number of years ago particular attention was attracted to this method of treating pleural effusions by an article which was published in the original columns of the *THERAPEUTIC GAZETTE*. Since that time the writer of this editorial has attempted this method of treatment in a number of cases without obtaining satisfactory results, perhaps because he had more confidence in other measures and resorted to them before the salicylate had an opportunity of doing good. In a recent issue of the *Archives Russes de Pathologie*, vol. iv, 1897, Poliakoff insists very emphatically upon the utility of the salicylate of sodium in the treatment of pleural effusions. He has never seen disagreeable symptoms produced by the administration of the drug under these circumstances, and recommends that it be given in cachet, and immediately after the ingestion of the cachet that the patient take a drink of some alkaline water. Should the dose of the salicylate seem to depress the heart, this may be avoided by the simultaneous use of a little caffeine. After the salicylate has been administered for three or four days its use is suspended for a day or two, and it is then renewed.

It would seem from Poliakoff's studies that the salicylate is particularly useful in chronic apyretic pleurisy. He records six cases in which this treatment was used. In five of these cases the salicylate produced results which were exceedingly satisfactory.

---

*THE ADMINISTRATION OF ANESTHETICS.*

---

Upon this topic, one of cardinal importance to every practitioner of medicine, there have lately appeared in the London *Lancet*

three lectures delivered by Frederic Hewitt, based generally on a wide experience as an anesthetist, particularly on 6657 administrations of anesthetics conducted at the London Hospital during the year 1897. On the first of that year Hewitt adopted a system of recording the cases of anesthesia, providing books and special tabular forms so that every instance of the administration of the narcotic in any part of the hospital could be properly noted. It is interesting to observe that out of the total number of cases nearly 3000 were of ether and more than 1000 of nitrous oxide. Chloroform was relied on solely in 677 cases, the A. C. E. mixture in 510, ether followed by chloroform in 293, nitrous oxide and oxygen in 240, and other successions in the majority of the cases unaccounted for. It will be noted that Hewitt has not confined himself to any particular method, but has had a sufficient clinical experience to speak with authority upon nearly all the combinations in common use.

As to chloroform, he states that within a few years it was the anesthetic in routine use, but that confidence in it has been shaken by experience. He particularly warns against the employment of certain recently devised chloroform inhalers. He states that for giving chloroform in the ordinary routine way there is nothing better than Skinner's mask.

Referring to the general effect of chloroform as an anesthetic, Hewitt states that, other things being equal, the stronger the patient the greater the trouble in giving the anesthetic. Deaths from chloroform are the most common in the middle period of life, when men are most vigorous, and more men die than women under this anesthetic. The drug is most lethal during the early stage of its administration, and a very large proportion of the accidents have occurred in connection with minor operations, which are most common in vigorous subjects. The explanation of this is dependent upon the fact that during the transient, very imperfect anesthesia, the muscular system is thrown into a condition of spasm, most marked in the most powerfully developed.

Hill and Barnard state that deaths which take place comparatively early in chloroform administration are usually due primarily to rigidity, struggling, and holding the breath; secondarily to a considerable quantity of the anesthetic being taken in during the succeeding respirations so that the right heart, already overfull, is paralyzed by the chloroform carried directly to it.

Referring to the practical administration of chloroform, Hewitt states that every breath should be heard or felt, that watching the chest or abdomen is a fallacious guide, and that it is of paramount importance to avoid all obstructions to breathing, except a very minor degree recognized by a softly snoring sound. In patients with perfectly free respiratory passages, and often following a phase of respiratory excitement, a condition of tranquil or almost imperceptible breathing may arise quite independently of the overdose of the agent. It indicates partial or moderate anesthesia and is of particular importance, because it is liable to lead to pallor and pulse feebleness, probably because the heart of the chloroformed patient is less able to meet the strain thrown upon it by the occurrence of feeble respiratory action than the heart of the patient under ether. Hence this type of respiration should be avoided, and a moderately snoring respiration when once induced should be maintained by the fairly free use of the agent.

Hewitt states that if snoring has never come on, or is allowed to disappear, it is a good plan to artificially induce it by gently pushing the lower jaw backwards. The results are that the breathing at once increases in force and circulatory depression is averted. In regard to the pulse Hewitt stated he was at a loss to understand the views of the Hyderabad Commission as to the desirability of systematically disregarding its condition until he saw Surgeon-Lieutenant Lawrie administer chloroform in his hospital. He noted that the anesthesia with which he worked was not so profound as that commonly induced in England, the conjunctival reflex being rarely abolished. Under such circumstances watching the pulse is evidently unnecessary; indeed, its indices may be distinctly misleading, as, for instance, its condition just before vomiting, when the feebleness will be construed by the inexperienced anesthetist as showing that the anesthetic should be removed, whereas it should really be pushed. When chloroform is pushed to its full surgical limit the pulse should be carefully watched. Arterial tension falls. A certain degree of pallor and a slow and rather feeble pulse are not necessarily indicative of danger; this condition often precedes respiratory failure and enables the anesthetist to avoid this later and more serious complication.

Hewitt states that there is much to be said in favor of the use of ether and chloroform in succession. The stage of rigidity and excite-

ment, which is the dangerous stage in chloroform, is safely passed over under the stimulant effects of ether. Having secured a proper degree of ether anesthesia, chloroform may be substituted, and there will result a better type of chloroform anesthesia than if this drug had been given from the beginning.

Hewitt has adopted this principle for several years and is able to use chloroform without the occurrence of those untoward symptoms which are bound to occasionally arise when this agent is given from the commencement of the administration. He regards this development in our methods as one of the most important of recent years. It is especially indicated when ether causes cough, embarrassed breathing, or the secretion of much mucus, or when the operation is likely to be a protracted one. Some practise is needed to know when and how to effect the change. The rule to be followed is that there should always be some evidence of the patient having emerged from ether anesthesia when the chloroform is applied. As a rule the conjunctival reflex should be present when the change is effected, and in abdominal operations this change should be made before the operation is begun. Very little chloroform will be required to keep up the proper degree of unconsciousness.

As a result of a very large experience Hewitt uses much less ether and much more chloroform than formerly. He holds that it is as safe to keep up the anesthesia of chloroform as that of ether, and that the risk of subsequent bronchial and pulmonary complications is undoubtedly reduced. He has often anesthetized according to this procedure the patients in the sitting posture, and in not a single instance has he been compelled to place them horizontally.

By his arrangement of cylinders he is able to administer nitrous oxide and oxygen in combination and to keep up the anesthesia for an almost indefinite time. The method is the safest at present known and is devoid of after-effects. The anesthesia is not so deep as that of other agents commonly employed; the muscular system is not so completely relaxed; nor is it possible always to completely abolish reflexes. He is not satisfied with it in severe surgical cases. His best results have been with rather debilitated women or children. Robust and vigorous male adults, especially those of alcoholic habit or excessive smokers, are not good subjects. In one case of breast excision

in which the anesthesia was kept up for thirty-five minutes, a good deal of vomiting followed.

Hewitt's observations concerning the use of nitrous oxide before ether are especially serviceable. This plan of anesthetizing is at times highly inapplicable and unsuccessful. Cases are seen in which there has been a narrow escape from fatal asphyxia. Muscular men of middle life who have become rather obese should never be anesthetized by this method. If it is employed only a small quantity of nitrous oxide should be used, and ether should be gradually added to it. The plan of administering a full dose of nitrous oxide and changing to ether is, however, very useful in children and in women, provided that there are no contraindications to ether in the patients.

The use of nitrous oxide, ether and chloroform in succession is warmly commended. The initial anesthetic, nitrous oxide, rapidly destroys consciousness and prevents struggling. The intermediate anesthetic, ether, is useful because the circulation will remain unimpaired by the strain imposed upon it should rigidity or suspended breathing arise before deep anesthesia, and because the stimulant effect produced by the ether lasts for a considerable time while chloroform is being given. Chloroform is administered because of the quiet and deep anesthesia which it produces, because of its great convenience, and because of the rarity with which bronchial and pulmonary after-effects are met with after its use. Hewitt states that given no special contraindications there is no better plan of anesthesia than this.

The A. C. E. mixture he commends for middle-aged and powerfully built men, with double chins and thick necks. It is first dropped upon an open Skinner's mask; after a couple of minutes a Rendle's mask with more of the mixture upon it may be substituted; and immediately any rigidity begins to show itself the Rendle's mask may be exchanged for an Ormsby's inhaler charged with ether. By this plan he has been enabled to successfully anesthetize without any difficulty many such subjects.

Of the total number of cases anesthetized by Hewitt there were thirteen which exhibited threatening symptoms. The four factors giving rise to dangerous symptoms are, he states, the anesthetic itself, the state of the patient, the posture of the patient, and the surgical operation.

In the first case which exhibited danger-

ous symptoms breathing stopped before the patient was thoroughly anesthetized. As the patient was greatly cyanosed ten ounces of blood were drawn, and the breathing immediately commenced. It is very common just before anesthesia is established for the breathing to become temporarily suspended. This is due to acts of swallowing, which are more tardily performed than when consciousness is intact, thus closing the glottis. In addition there may be general muscular spasm. In the vast majority of cases this impaired breathing comes on just before stertor and passes off spontaneously, or may be made to do so by removing the inhaler, rubbing lips with a towel, or pushing the lower jaw forwards. In more obstinate cases, in which the jaws are clenched and the neck muscles are rigidly contracted, it may be necessary to separate the teeth and to pass the finger to the back of the pharynx, when breathing will recommence. Unless this condition is remedied it may pass on to a dangerous or even fatal degree of asphyxia.

The second case presenting dangerous symptoms was one of disease of the heart in which ether was given, full strength by the Clover inhaler, since the patient was well built and of alcoholic habit. This method commonly produces in these patients the most satisfactory anesthesia. In cases of heart disease in which there is evidence of want of compensation, all asphyxia methods should be carefully avoided. Nitrous oxide alone or in conjunction with ether is equally unsuitable. The best anesthetic in such cases is the A. C. E. mixture, or if for any reason ether should be preferred, it should be given by an open inhaler which does not by eliminating oxygen throw extra work upon the right side of the heart.

When the patient is of full habit he naturally becomes purplish or bluish under ether; sometimes he becomes ashy or livid, and this must always be regarded as an indication of danger. Moreover, whenever the lids are only partly closed and the globes of the eyes are turned slightly upwards so that more of the sclerotic than usual is visible, attention should be directed to the patient's general condition. Widely opened lids with the globes fixed in their normal horizontal axes may be met with in the most satisfactory types of anesthesia. Flaccid, nearly closed lids, displaying subjacent sclerotics, are usually indicative of an unsatisfactory condition.

There was one case of severe bronchitis following ether administration, and one inter-

esting case of suspended breathing during recovery after ether administration for putting up of fracture of the femur. So far as the administration of the anesthetic went, there was very little to note beyond that a great deal of mucus was secreted. When the anesthetic was discontinued, the patient became rigid, with clenched jaws, cyanotic, obstructed breathing incidental to commencing vomiting. Prying open the jaws was performed, the tongue forceps applied, and the finger passed to the back of the throat. Respiration was not started by any of these measures. Tracheotomy was then performed, and directly this had been done a great deal of mucus escaped from the tube. Hewitt states that patients should be turned on the side immediately the anesthetic is discontinued. By this procedure mucus will tend to flow out of the mouth, the tongue will gravitate into the cheek, and stertor will cease.

Of the 6657 cases of anesthesia there were only three in which the anesthetic could in any way be held responsible for the fatal issue, and only one in which the anesthetic was the sole factor.

In a case of appendicitis following typhoid fever the patient apparently died of bronchopneumonia thirty-four hours after operation. Hewitt holds that the chances of pulmonary complications would have been less if chloroform or the A. C. E. mixture had been given, and that from this experience it is fair to infer that the unusual cyanosis met with during the administration might with advantage have been taken to indicate that a change from ether to chloroform should have been effected.

The immediately fatal case occurred under chloroform and during the period of preliminary excitement.

As to the gastric after-effects of anesthetics other than nitrous oxide, in 275 cases in which this was noticed there were none in 109, slight in 109, moderately bad in 35, and severe in 22. Calculating on a percentage basis, it is noted that 36 per cent. of the ether cases had no after-effects; while 32 per cent. of the ether cases followed by chloroform were similarly fortunate; 7.2 per cent. exhibited severe after-effects after ether. Patients are more apt to suffer from slight after-effects when ether has been used, but the chances of protracted vomiting are greater when chloroform has been administered. There can be no doubt that abstinence from food for at least four hours before operation should be enforced. Clear soup or beef tea

is the best form of nourishment before operation. The practise of giving a patient beef tea three hours before operation is open to objection. The stomach should not only be emptied, but digestion should have been finished for some little time.

A tabulation shows that the severity of the after-effects is markedly influenced by the continuance of the anesthetization. As to the prevention of the gastric after-effects, in addition to previous regulation of the diet it is essential that the bowels should be thoroughly evacuated; this is accomplished by administering a purgative on the night before the operation and an enema on the morning itself. The patient should be rendered anesthetic as rapidly as possible; a deep anesthesia, free from swallowing movements, should be maintained. The head should be kept to the side for the escape of mucus and saliva, and the mouth should be frequently wiped out. The patient when in bed should be turned well upon his side and the bed should not be moved, and the room should be kept quiet. No nourishment should be given until the patient himself asks for it.

If nausea, retching or vomiting be present the patient should be given at intervals two or three ounces of very hot water to drink. The taste of ether is best overcome by moistening the lips with lemon juice. If there appears to be a neurotic element present, enemata of twenty grains of bromide of potassium in two ounces of water will often answer well. The inhalation of vinegar from a towel is very useful in arresting vomiting, as is also the application of mustard leaf to the epigastrium.

This communication of Hewitt's is extremely important, as it is founded upon the careful, minute, detailed observation of an accomplished and widely experienced anesthetist. The diversity of his methods and the multiplicity of his apparatus do not commend themselves to an American surgeon. One important lesson, however, taught by his paper is that there are merits in ether, chloroform, and nitrous oxide; that each has its appropriate place in surgery; and that in place of the slavish adherence to routine it would be wise to judiciously select in accordance with the condition and temperament of the patient. His practical observations upon certain difficulties that arise during anesthetization, his strictures concerning the employment of chloroform and nitrous oxide in the robust, are useful. His reasons for substituting ether by chloroform will scarcely be

conclusive to American surgeons, save in exceptional cases—*i.e.*, those with a tendency toward pulmonary congestion. Under such circumstances the following of Hewitt's plan may well be commended. It would perhaps have been well to have called attention to Laborde's method of traction upon the tongue in restoring respiration during the late period of anesthesia and flagellating the epigastrium by means of wet towels.

The reversed abdominal motion—*i.e.*, retraction of the epigastrium and abdomen—upon expiration in diaphragmatic paralysis is frequently observed when the anesthetic has been pushed too far. Hare and Martin showed in experiments that the diaphragmatic muscle is usually the first to be paralyzed, and have frequently called attention to the importance of carefully watching the abdomen to see that the diaphragm is properly performing its function and is not being sucked up into the chest with each inspiration, thus preventing the lungs from properly expanding. The attention which Hewitt calls to the condition of the eye is not in accordance with that held by the American surgeons; but it must be remembered that the Clover apparatus is not commonly employed by American anesthetists. It is very common to see the eyeballs turn up and the lids half open. We have learned to regard wide dilatation of the pupil as the only important ocular symptom which is likely to indicate grave danger. In the great majority of anesthetized patients the eye rolls up as it does in sleep.

The advice given to push the jaw backwards for the purpose of inducing slight stertor seems to be unwise. With experience the anesthetist soon learns to recognize the quiet, absolutely free breathing which is an index of the perfect anesthesia. Pressing backward of the jaw always obstructs the respiration to a greater or less degree, and the only manipulation which should be practised upon it is to lift it forward and to extend the head for the purpose of rendering the air-passages freer.

A great disadvantage of chloroform to which Hewitt has not called attention is its lethal effect upon the kidneys. There is some superstition to the effect that ether is to be avoided when a patient who requires anesthesia has any form of nephritis. All the observations of recent years have proven apparently beyond contravention the falsity of this doctrine. In Hewitt's large number of cases there is not a single death

which occurred during the administration of ether, although this anesthetic was given in a greater number of the sum total of his cases. Of the very few who took chloroform one died absolutely from the anesthesia, since the fatality occurred in the early stages of its administration.

## Reports on Therapeutic Progress

---

### *PNEUMONIA TREATED BY HEAT OVER THE SPINE AND BY THE INHALATION OF PURE OXYGEN.*

The *Boston Medical and Surgical Journal* of December 2, 1897, contains an article on pneumonia by B. O. KINNEAR, of New York. He tells us that the treatment of pneumonia in the congestive stage, and that of red hepatization, by heat over the dorsal sympathetic ganglia is but little known as yet to the profession, though it has been occasionally brought to their notice during the past thirty years. It is Kinnear's object to demonstrate what heat so used will accomplish in this disease in its early stages, and to give evidence of the soothing, supporting and life-restoring power of properly combined and prepared oxygen.

It appears to the writer that the most efficient treatment in the early stage of the disease is to contract the arterioles in the inflamed area, as well as throughout the upper body, because from post-mortem appearances we know that in cases of pneumonia where much of the lung is involved there is also found effusion upon the pleural surface, pericarditis, and even the upper part of the peritoneum may be found covered with lymph; while delirium and cerebral meningitis may be present.

How then may we successfully accomplish this much to be desired end?

Kinnear has found that very rapid and satisfactory results can be obtained by applying the spinal hot-water bag, or its equivalent in heat and moisture, over the dorsal sympathetic ganglia. By the application of heat over these knots of nervous tissue in this region he has, he states, over and over again, during the past sixteen years, subdued nearly all the acute forms of inflammation affecting the respiratory apparatus.

A double-columned hot-water bag may be applied, or two rows of flannel may be used (being first dipped in water no hotter than 120° F.) instead of the hot-water bag; the space of one inch should be left between the

rolls, so that the heat will not cover the spinal vertebrae direct. One yard of flannel, eight inches wide, rolled evenly from each end toward the center until the space of one inch remains between the rolls, may then be sewed so that they will not unroll. They will answer if the hot-water bag is not at hand, and may be made the means of saving many lives in the earlier stages of all inflammations of the respiratory passages. They should be wrung out after dipping in water at 120° F., and then quickly applied between the shoulders, covered with a thick dry towel, and the patient told to press against them. The application when flannel is used should be changed every twenty minutes, until decided relief is obtained to the breathing, the pain, the flush of the face, and the bounding pulse. It may then be removed until there are signs of a renewal of the symptoms, when it can be reapplied, and will be found at once to check them. The hot-water bag used in this way in active congestions and early inflammations will always reduce the temperature and the pulse, and excite the sweat glands to action, thus giving relief to the symptoms; evidencing also by auscultation a speedy progress toward recovery, and therefore a return to normal of the caliber of the pulmonary capillaries in the stage of congestion—and in the condition of red hepatization, a rapid resolution or reabsorption of the inflammatory exudation.

In bronchitis, in pneumonia alone or when accompanied by pleurisy, in acute laryngitis, and in the frequent pleurisy of phthisis, the author has quickly controlled the inflammation by this means.

In some people Kinnear has found great prostration to follow the rapid reversal of the inflammatory process in respiratory diseases; and he believes this to be due to some extent to the shock to the nervous system, both of the attack and also that caused by the sudden restorative change. In the past he had often wished that he possessed some agent which would improve nutrition, stimulate the nerve centers, and aid restoration of normal inspiration by rapid oxidation of the blood and the tissues, while conquering the inflammation by the hot-water bag.

Such an agent Kinnear thinks has been found in the inhalation of pure oxygen properly diluted by combination with a gas of lighter specific gravity than oxygen. Pure oxygen when used alone is too dense in its specific gravity to be absorbed by the capillaries, being also too powerful an oxidizing

agent, and very irritating to the mucous membranes, especially in subacute forms of inflammation.

The gas which has been found best suited to dilute the oxygen is nitrous monoxide, and the formula used by the London Oxygen Hospital is considered the best by all leading writers upon oxygen. It is pure oxygen two parts, one part of nitrous monoxide, and a small equivalent of ozone added to keep the oxygen fresh. This employment of ozone does away with any objection which might be made to gas compressed in cylinders, as it prevents rapid deterioration.

Kinnear cannot speak too emphatically upon the proper formula and the quantity of the gas, because only by strict attention to both can we ameliorate and subdue diseased conditions.

Oxygen as a therapeutic agent is but little understood by the medical profession; and it is a very serious error to suppose that the ordinary commercial oxygen manufactured by calcium-light makers is a proper agent to be employed for therapeutic purposes. It is often saturated with chlorine and other deleterious gases, which, being exceedingly poisonous, are most injurious to the patient. The physician should therefore obtain the very best quality.

#### THIOSINAMINE.

In the *New York Medical Journal* of November 6, 1897, Dr. Tousey makes a further report on the therapeutic uses of thiosinamine and calls attention to his article published in the *New York Medical Journal* of May 2, 1896, in which he stated that he had begun his study and use of this drug in 1894, and that, so far as published, his were the first cases of keloid treated with it. The writer then stated that while the number of cases was small the results had been positive.

He writes further upon the subject in order to answer a number of inquiries, and also to record the ultimate results in the cases already described. In addition thereto, a number of later cases in his own practise and that of others will be reported.

The drug itself is derived from oil of mustard seed, and belongs to the same chemical group as urea:

It is crystalline and does not keep well in an

aqueous solution. It is amply described in all modern works on chemistry and in Merck's price list of drugs.

Thiosinamine first appears in medical literature as one of the things experimented with in the hope of finding a cure for tuberculosis. In this it proved an addition to the long list of failures. It was studied by Hebra, Van Hoorn, Richter and Zedziak as to its influence upon tuberculous processes, its bacteriology, and its physiological action, notably upon the blood. They also tested its therapeutic action in several of the conditions mentioned below.

These investigations showed it to have no curative influence upon tuberculous processes; not to be even a feeble germicide, but to have two properties from which Tousey made the deduction that in this drug we possessed the long-sought means of cure for keloid. One of the observations which led to this discovery of the writer's was that its use was followed by the softening and relaxation of the deforming cicatrices left by lupus and the consequent cure of extreme cases of ectropion and the like. Another was that its hypodermic administration produced an immediate disintegration and elimination of white blood-cells, so that the number present in the blood fell to one-third the normal. This was followed by a leucocytosis, or increase beyond the normal, persisting for forty-eight hours.

The answer to the question, How does the writer explain its effect upon keloid? is this: This tremendous cellular activity in the circulating medium calls forth a coordinate activity in the leucocytes and fixed connective tissue cells throughout the organism, and an increased removal of effete or lowly organized material by way of the blood and lymph channels. This view is strengthened by the recorded observations of diuretic action when beginning its use. Accurate observations made upon ward patients in German hospitals showed it to be an active diuretic and to hasten the absorption of fluid effusions. The first of these effects has also been observed by a correspondent of the writer's in Philadelphia. It should be stated here that where he has quoted from private communications he has withheld names and details, so as to enable each gentleman to report his own results when he shall have formed his final opinion of this method of treatment.

For nearly a year past Tousey has been using and now recommends a hypodermic solution made by dissolving ten parts of

thiosinamine in one hundred parts of a sterilized mixture of water and glycerin. This solution keeps well and is non-irritant. He injects twelve or fifteen minims, as a full dose, into the muscles, triceps, or glutei, every three days. Others have used three grains of thiosinamine as a usual dose, and in a great many cases this is well borne. The writer thinks the dose should be gradually determined for each individual case. In the author's experience doses much larger than fifteen minims of the solution caused a slight feeling of nausea after each injection.

Tousey is in a position now, after a wider experience with it, to state most positively that the use of this drug is free from deleterious effects of any kind. He realizes that before it can be established as a successful treatment for keloid and the like, equally favorable therapeutic effects must be obtained by many other observers. These corroborative observations are being reported to him constantly.

Too large or too frequent doses might cause slight nausea, and too long continued use without intermission might produce headache and malaise; but neither of these has occurred in the writer's cases. Carefully conducted, the treatment produces a general tonic effect, and his cases of keloid have not lost a day from work or business during the treatment.

The author's advice has been asked about its use in the treatment of corneal opacities. He states that he would inject twelve minims of the solution into the triceps every three days and continue with the same dose until at least twenty-seven injections had been given. Marked improvement in vision may be promised, but the improvement in appearance is not so striking. In every case, therefore, this treatment should be used for definite and serious impairment of vision, and the acuteness of vision should be carefully measured and recorded before and after treatment. An observation of the writer's own, recorded in this paper, will show his reason for believing that any benefit obtained in the absorption of cicatricial tissue or the like by this drug is a permanent one. As mentioned in his first article, a number of cases of corneal opacity have been successfully treated by Hebra and by Richter. In a case reported by the former the patient before treatment could hardly avoid collisions with people on the street, and afterward could read the time by the high city hall clock in Vienna. Hebra states that a large number of cases of

mild impairment of vision from corneal opacity have been entirely cured by treatment with thiosinamine at the Rudolf-Spital in Vienna.

A recent case communicated by an oculist of Philadelphia showed very marked improvement in vision and corroborated earlier observations as to diuresis and as to increase in appetite and weight during treatment. There occurred after one injection slight temporary anesthesia of a portion of the forearm.

The possibility of the last mentioned occurrence was mentioned in the writer's first article, and was there attributed to a mechanical injury to a cutaneous branch of the musculo-spiral nerve. Similar cases are on record where ether or antipyrin has been given by the hypodermic method.

In this connection should be recorded an unfortunate case in the hands of one of the writer's correspondents: The patient suffered from deforming syphilitic cicatrices of the neck and face. The doctor injected thiosinamine into the triceps, using the strictest antiseptic precautions. Shortly afterward the arm became swollen and painful, and death ultimately ensued from septicemia.

Such a case brings forcibly to mind the necessity for eternal vigilance in the employment of the hypodermic method of medication, but is so rare as not to lead any one to abandon its use where it seems to be the best means of introducing a drug into the system.

In a recent case of the writer's he administered thiosinamine by the mouth. Three grains was given in capsule every day for eight weeks without any disturbance of any sort, and with the therapeutic effect sought for. This is the only case in which he has given it by the mouth, but he has seen no reason why this, the simplest, may not prove to be the best method of administering the drug. Two of his correspondents have used an aqueous solution hypodermically, and report less pain and equally successful results.

The use of thiosinamine for corneal opacity should be limited to cases in which there is no danger of fanning a latent inflammatory process into an active one. In the case of the eye, such an effect would necessarily be detrimental; but elsewhere it is sometimes of benefit. The author cites a case mentioned in the first article: the use of this drug in an old latent case of osteomyelitis of the tibia started up suppuration, resulting in the extrusion of an old sequestrum and definite healing.

One of the writer's correspondents reports the cure or clearing up of a cataract under thiosinamine treatment. It certainly was innocuous; and if this observation should be verified by other physicians in other cases of cataract, it will indeed be a most wonderful thing.

For keloid, cicatricial contractures, and hypertrophied scars, further experience in its use has proved its utility.

In the author's first published case of keloid the patient remains now, three years after treatment, entirely free from recurrence, and shows only a broad, flat, flexible cicatrix.

[See the THERAPEUTIC GAZETTE for July, 1896, and page 403 for 1897.—ED.]

#### ALCOHOLIC STIMULATION IN CONTINUED FEVERS.

What are the indications for the use of alcoholic stimulants in such febrile diseases as typhoid, grippe, pneumonia or septicemia? This is the question put and answered by CABOT in the *Boston Medical and Surgical Journal* of December 2, 1897.

There are many who regard the existence of one of these febrile diseases as of itself a sufficient reason for giving alcoholic stimulants. For example, in Wood and Fitz's "Practice of Medicine" it is laid down that "alcohol in some form should be used in every case of typhoid from the beginning, unless there be some very strong reason for refusing it, as where there is a distinct heredity towards drunkenness." Many who might not agree to this course in typhoid believe in using alcohol in every case of pneumonia, whatever its nature, and in all severe septic and pyemic processes the author supposes that the majority of good practitioners in this vicinity would prescribe alcohol as a matter of routine. From this point of view, the diagnosis once established, the exhibition of alcoholic stimulants is a matter of course.

On the other hand, there are in many modern text-books signs of a reaction against this wholesale and routine use of stimulants. For instance, W. Gilman Thompson, in his new work on dietetics, says: "I am inclined to prescribe very much less alcohol than formerly;" and again: "The routine employment of alcohol in typhoid is to be deplored." Pepper, in the edition of 1894 of the "American Text-book of the Theory and Practice of Medicine," says: "Until recently the symptoms of alcoholic overaction (in typhoid)

were often mistaken for advancing debility, and regarded as an indication for still more free stimulation."

Of modern authorities Strümpel is the only one who distinctly disbelieves in the use of alcohol in any of the diseases above mentioned. Even in pneumonia he does not give alcohol except to patients who have become habituated to it before their illness. "We could never satisfy ourselves," he says, "of the often praised action of alcohol on the heart."

Between these two extremes—the routine use, and the absolute avoidance of alcohol in continued fevers—falls the practise of most of us. The usual opinion is that there are certain indications for the use of alcohol in such cases. What we want to bring out in this paper is that many of us are not as clear or as consistent as we ought to be as to just what we expect to gain by stimulation, and as to the reasons for its use in any particular case.

For example, Cabot thinks there is a fairly wide-spread impression among us that alcohol is itself directly inimical to the toxemia which forms the chief danger in acute infections.

Does this impression rest on any satisfactory experimental basis? The writer has never heard of any such. If it could be shown that the use of alcohol increases the germicidal power of the blood, or of the power of the kidney to excrete toxins or precipitate them in the stomach, we should have a satisfactory reason for giving stimulants, as, for instance, most surgeons now give them in septic cases. There would then be good reason for giving stimulants even if they did not improve the heart's action, the digestion, or any other function of the organism. But, so far as known, there is no experimental evidence that the ingestion of alcohol does increase the antitoxic or bactericidal power of the blood, and there is a certain amount of evidence that so far from increasing the ability of the kidneys to excrete toxic products, alcohol has just the reverse effect. We know that alcohol precipitates snake poison in the stomach where it is excreted, but the writer is not aware of such evidence as regards other toxins. He has heard surgeons and others express a belief that it is no harm to stimulate a septic patient even to the point of making him drunk. As to the wisdom of this course the following experiments are relevant:

1. In the *Comptes de la Société de Biologie*

for 1895 (p. 51), Wurtz and Hudels report experiments on fourteen rabbits and seven guinea-pigs, which were given enough alcohol to make them drunk, and then killed, and their blood examined for bacteria. Over one-half the cases showed the presence in their blood of streptococci, colon bacilli, proteus vulgaris, and various anaerobic organisms.

The control animals, to whom the same dose of alcohol had been given, recovered from its effects, showing that the inroad of bacteria in the autopsied cases was not due to any moribund condition from a lethal dose. They were simply drunk and not dangerously poisoned.

If large quantities of alcohol make bacteria enter the blood in animals, why may it not have a similar effect in sick men? Are we likely, then, to benefit a septic patient by making him drunk?

2. Again, take the question of the excretion of toxins by the kidney. It is well known that in most acute infectious diseases, where the patient is doing well, the urinary toxicity is greatly increased, and this is taken to show that the kidneys are aiding in the fight against the disease by excreting the poisons produced by the infectious agent. Kellogg found that the use of alcohol, so far from increasing the urinary toxicity, greatly decreased it. The writer does not vouch for these results, but offers them for what they are worth. There is no doubt that cold bathing in typhoid does increase the urinary toxicity, as has been shown by Roque and Weill.

Apart from the question of the action of alcohol as an antitoxic or bactericidal agent, the following indications for using it in continued fevers are stated in most text-books:

1. Persons long addicted to its use should not be deprived of it in febrile diseases. On this point there seems to be no disagreement.

2. It may be the only form of food which the patient can and will take.

3. Sudden collapse or great prostration from any cause is generally agreed to call for stimulation.

As to these three indications the writer thinks most physicians would agree. But the great majority of writers go further and recommend that:

4. Any serious complication, such as hemorrhage or perforation in typhoid, severe nervous symptoms like delirium—in fact, anything that shows an especially severe

case—should be considered an indication for stimulation.

5. Persons over forty years of age and persons of feeble constitution are believed by most writers to need stimulation in case they catch any severe infectious disease, like typhoid or pneumonia.

On the other hand, Ringer's views on the use of alcoholic stimulants are copied into many text-books, and they conflict with the belief that a severe or complicated case or one occurring in a feeble person should always be treated with stimulants. Ringer says in substance: "If after the use of alcohol we see the pulse become slower, the skin and tongue moister, sleep better, nervous symptoms less marked, breathing less hurried, food better taken—the alcohol is doing good. Not otherwise."

Now, if this be true, we cannot say that severe or debilitated cases need stimulation, but only that they may need it, or that they need it in case it turns out to do them good. Now this is where the writer thinks many of us err. We do not watch the action of alcohol as we do that of other drugs which may do harm. We often give it as we might give malt, and not as we give digitalis or calomel. When we give a diaphoretic or a purgative, we look for its definite action; if we do not get it after a sufficient dose, we do not continue the drug. But the writer has repeatedly seen alcohol given whether any good effects appeared or not, with a general idea that it must be doing good since it is a food and a stimulant. But in many cases it does not act as a stimulant—in any dose; does not slow the pulse, moisten the tongue, or decrease restlessness and delirium; and other food is so well taken that it is not needed as a food,—yet we go on using it under a vague impression that it helps the patient to fight his disease, makes him feel better perhaps, and at any rate cannot do any harm. Cabot enters a protest against such treatment, which he sees constantly administered in our hospitals and elsewhere. He believes, with Pepper, that the symptoms of alcoholic poisoning are "often mistaken for advancing debility and regarded as an indication for still more free stimulation."

There is a pernicious idea which has been repeatedly advanced by prominent physicians, that if the smell of alcohol is not present on the breath the amount of alcohol given must be doing good. But alcohol is not excreted solely by the lungs, and its ill effects can be shown, as Ringer and others have pointed

out, by other symptoms besides the smell of the breath.

It seems to the writer that what is most needed at the present time in order to improve our therapeutic use of alcohol is more experimental evidence on two points: (1) The effects of alcohol on the toxicity of the urine, and on the antitoxic and bactericidal power of the blood; (2) the effects of treating acute infectious diseases without alcohol.

The writer has often thought that therapeutic progress is seriously hindered by the fact that every case is given the best treatment known. He accounts for the long persistence of the bleeding treatment by supposing that since every patient was given the best treatment known—namely, bleeding—physicians had no chance to see how the disease would do without the treatment. Similarly, at the present day, so few of us have ever seen a severe case of sepsis or pneumonia treated without alcohol that it is very possible that some of us may attribute to the disease (as Pepper says) symptoms really due to the treatment. The writer has often been struck with the close resemblance between delirium tremens and some of the symptoms of severe febrile cases treated with the best known alcoholic stimulation.

In 1864 A. L. Loomis treated 600 cases of typhus fever without alcoholic stimulants as an experiment. His mortality record was six per cent.; the previous record in the same epidemic in cases treated with stimulants was twenty-two per cent.

N. S. Davis claims to have treated 1000 cases of typhoid fever without alcoholic stimulation, with a mortality of five per cent.

Kellogg, of Battle Creek, states that he has treated eighty-two cases of pneumonia without alcohol, with a mortality of 4.9 per cent.

The author states that he is aware that statistics can lie, and he is not prepared to say, as Strümpel does, that we should give up alcoholic stimulation in fevers; but he does think that we need a broader experimental basis for our practise of and use of stimulants simply because the case appears to be very severe.

In conclusion he believes that alcohol, like other drugs, should be given to accomplish a definite therapeutic result, and if no signs of that result appear the drug should be withdrawn. Experimental evidence is much needed: (a) As to the effects of alcohol on the toxicity of the urine and the bactericidal power of the blood; (b) as to the result of treating acute febrile diseases without alcohol.

**POTASSIUM CHLORATE POISONING.**

P. JACOB (*Berliner Klinische Wochenschrift*, July 5, 1897) records a fatal case. A patient aged thirty-nine was admitted almost comatose, thirty hours after taking about twenty-five grammes of this drug. The face, ears, fingers and toes were blue. There was much dyspnea, and the pulse was thready. Camphor injections were given, and the stomach washed out with water to which sodium bicarbonate had been added. Venesection was performed on two occasions, and 1000 cubic centimeters normal saline solution was infused. Some considerable improvement was noted on the third day. Fifty cubic centimeters urine of a brown-red color was drawn off, and was found to contain both albumen and blood. From the time of admission a marked methemoglobinuria existed, but after the second day a distinct hemoglobinuria. Six days after taking the poison the patient died suddenly and unexpectedly. Only an incomplete necropsy could be made fifty hours after death. The spleen was enlarged, the lungs deeply engorged with blood, and the kidneys swollen. The changes in the blood were interesting. There was a very marked leucocytosis at first. The red cells were paler than usual, and showed marked degenerative changes. The leucocytosis gradually diminished, so that on the day of death the leucocytes did not exceed the normal, but the changes in the red cells gradually increased, so that eventually hardly a normally colored red cell was to be seen. The red cells which escaped the destructive changes nearly all showed poikilocytosis. The author's observations thus agree with those of Riess and Krönig. The hyperleucocytosis is a reactive change. The author would go so far as to say that the use of potassium chlorate, even as a gargle, should be entirely given up and forbidden. Even in small doses it is a severe blood poison, and may produce a hemorrhagic nephritis.—*British Medical Journal*, Nov. 20, 1897.

**CHLOROFORM AND ETHER.**

In the *Boston Medical and Surgical Journal* of December 23, 1897, Dr. KEEFE contributes an able, practical paper on these anesthetics. He thinks a careful review of this subject would enable us to draw the following conclusions:

1. Statistics are at present of little or no value in deciding as to the relative danger of

chloroform and ether, because, as the author has shown in a previous paper, the deaths under both bear a lower ratio to the inhalations than the sudden deaths in those who had not taken an anesthetic bear to the population.

2. Ether is a safer anesthetic in proportion as it is weaker, bearing a relation to chloroform of about one to five. The danger of chloroform is not so much inherent to it *per se* as to its relative greater strength and the greater care and experience required in its administration. He states that he would trust almost any physician to give ether, but not one in twenty to administer chloroform; just as any child can handle a toy engine, but not every man can handle a steam locomotive.

3. The difficulties with both chloroform and ether in the presoporose stages are, in nearly all cases, due to respiratory spasm, and the consequent heightened arterial tension and venous congestion. This is very likely to be unduly prominent in the brain on account of recumbency, and the few muscular fibers in its vessels in comparison to the general circulatory system. For this reason it is neither so well able to resist the onset by contracting its arteries nor to empty itself.

4. In the post-stertorous stage, after long application, the death is most likely to be caused by anemia and cardiac paralysis.

5. The best medicine for the first kind of interference is amyl nitrite, belladonna, and strychnine; and for the second, digitalis and strychnine, supplemented by electricity and all the other movements recommended by Dr. Hill.

6. Were the writer asked for the greatest advantages ether has over chloroform he would say: The anesthesia of ether is loud and lifelike, hence any accident or interference is noticeable on the instant; whereas chloroform produces so quiet a sleep that the patient seems on the border-land of the grave, and there is not so distinct a warning of accident until too late; consequently it requires a degree of vigilance and attention that few possess. Moreover, the administrator, if conscientious, feels that he assumes a greater responsibility than the operator.

7. Chloroform is a more satisfactory anesthetic for short operations, where the sopor need not be renewed or continued; for obstetrics, where the anesthesia need not be complete; and for patients with lung or kidney disease, and children.

8. Ether is pleasanter and safer (for the vast majority of physicians) to continue the

anesthetic state after having been induced by chloroform.

9. He does not believe there is any well marked difference in the manner of death under ether or chloroform; the stage of the anesthesia has more to do with it than the agent.

#### THE DIAGNOSIS AND TREATMENT OF HEMATEMESIS.

Professor ROBIN, of Paris, in an article published in the *Medical Press and Circular* of December 22, 1897, discusses this interesting and important subject. He tells us that in simple ulcer of the stomach, which might well be called *ulcus acidum*, the ulceration, and therefore the hematemesis also, has been preceded by a period of gastric hypersthenia. The preventive treatment of hematemesis from this cause will, therefore, consist first of all in the treatment of the gastric hypersthenia. Next to this, we must deal with the ulcer itself. The prehemorrhagic period is generally of sufficient duration to give one time for intervention. According to Cruveilhier's law, all solid food must be given up, and the absolute milk diet must constitute the basis of the treatment; milk in such cases is not only a harmless article of food, but also helps in the cure, tending to neutralize the acids and exerting also a sedative action on the hydrochloric acid secretion. The guiding rules of this milk diet are simple enough. The patient should take at least three quarts of milk a day, in five portions, at regular intervals, so as not to overstimulate the digestive functions. The milk should be taken cold, and preferably unboiled (if it be possible to procure a perfectly healthy milk); it should be mixed with a little lime water. This milk diet ought to be continued for six months at least, even when no further morbid symptoms supervene.

Several objections have been urged against the milk diet. It has been alleged to dilate the stomach, already rendered prone to dilate by the disease itself, but true dilatation in such cases is quite exceptional, and is more apparent than real; there is, in fact, only some distention due to spasm of the pylorus, this giving rise, by reflex action, to acid hypersecretion. The milk diet is in such cases the treatment of election; it does not increase the distention of the stomach, but tends to diminish it.

Von Leube recommends a different mode of treatment. The first indication, in his opinion, is to wash out the stomach, in order

to free it entirely from all fermenting matter, which is apt to exert a deleterious influence on the future evolution of the ulcer; next he injects an alkaline solution, in order to neutralize the contents of the stomach; lastly, he pours in an emulsion of bismuth. The bismuth is deposited on the walls of the stomach, constituting a regular dressing of the ulcer, which thus tends to heal up. Von Leube's method is certainly rational and may be worth a trial. The writer, however, objects to the introduction of a tube into an ulcerated stomach, this being an essentially risky and dangerous maneuver, apt to be followed by severe hemorrhage. This assertion is not theoretical. Cornillon and Duguet have published some well known cases in which the introduction of the tube was followed by fatal hemorrhage, and it is, after all, quite as easy to swallow the bismuth, which may prove useful when associated with an absolute milk diet.

The following powder will act at the same time on the ulcer, on the hyperacidity, and on the pain:

℞ Magnesiæ, 20 grains;  
Bismuth subnitratiss,  
Sodii bicarbonatis, of each 15 grains;  
Pulv. opii, 1 grain;  
Sacchari lactis, 1 grain.

For one powder. One or two powders a day, in one dose, in a little water.

Great care must be taken to keep the bowels open; calomel and jalap are useful for this purpose.

When we are called to a patient who is vomiting blood, we must at once remove the clothes, put him to bed with his head low, lying on his back, and recommend him to remain perfectly quiet. Inject hypodermically some ergotin into the skin over the epigastrium, and apply ice to the same region. Give from one to two grains of extract of opium, and then, every two hours, one tablespoonful of this mixture:

℞ Ext. ergot fl., f 3 iij;  
Acid gallici, gr. xxx;  
Ext. opii fl., ℥ xl;  
Syrup terebinth, f 3 j;  
Aquæ aurant. flor., q. s. ad f 3 vj.

Mix.

Continue the use of this mixture until the hemorrhage has entirely ceased.

Various complications may arise which will have to be dealt with.

In the event of syncope, have recourse to the ordinary means: horizontal position, head low, amyl nitrite, injections of ether or of Hoffmann's anodyne, flagellation, mustard

plasters to the legs; as a last resource, transfusion, which sometimes has a wonderful effect.

When the patient is in danger of suffocation from the passage of blood into the larynx, introduce your fingers into his mouth and practise rhythmical traction on the tongue.

When there are symptoms of acute peritonitis, possibly indicative of perforation, prescribe absolute immobility, extract of opium internally, and injections of morphine over the epigastrium.

The patient may suffer from incoercible vomiting. This must be stopped as rapidly as possible, seeing that it keeps up, or even increases, the hemorrhage. In addition to the classical treatment of this complication, you may prescribe:

- ℞ Picrotoxin,  
Morphine hydrochloratis, each gr. j;  
Atropinæ sulphatis, gr. 1-5;  
Ergotinæ, gr. xv;  
Aquæ dest., f 3 iv;  
Spt. vini rectificati, q. s. to dissolve.

Mix. From eight to ten drops in a little water.

In addition to these accidents, the hæmatemesis may be followed by others. The blood which has not been vomited may undergo putrid fermentation either in the stomach or in the intestine, all the more easily in the latter organ if the patient be constipated. This constitutes a serious risk of autointoxication; the existence of this complication may be inferred from a fetid odor of the last-vomited matter and also of the breath of the patient. This condition is effectually dealt with by clearing out the bowels, both by means of enemata (with glycerin, or with a tablespoonful of sodium hypochlorite) and purgatives.

When the patient has survived the hæmatemesis and the immediate and more remote complications, he still remains, as a rule, markedly anemic and weak. The normal treatment of this condition by means of more strengthening food being impossible, or at any rate contraindicated by the very cause which brought it on, it will be necessary to have recourse to medicinal agents.

In such a case the author prefers the perchloride of iron, which is both hemostatic and tonic; the other salts of iron are apt to determine congestion and thus favor a recurrence of the hemorrhage. The iron should, of course, not be administered until the patient has ceased taking gallic acid.

In eight or ten days stop the perchloride, as it may prove irritating to the mucous

membrane if continued too long. It may then be replaced by the protochloride (which is probably transformed into perchloride in the stomach) in association with cinchona and rhubarb, as follows:

- ℞ Ferri protochloridi,  
Extract. cinchonæ fl., of each gr. ij;  
Pulv. rhei, gr. j.

Mix. For one pill.

The patient to take one of the pills with each of the two principal meals.

#### NOTES ON THE TREATMENT OF TYPHOID FEVER.

In an article in the *Philadelphia Polyclinic* of December 4, 1897, with the above heading S. SOLIS-COHEN tells us that should a routine treatment of typhoid fever have to be pursued, there is no question that least harm and most good will result from the employment of systematic bathing in cold water after the method of Brand. But this treatment is not always necessary, nor is every case bathed best treated by undeviating adherence to Brand's method. As the writer had the pleasure of advocating the Brand system and of employing it according to his then limited facilities before many of its present advocates had seen fit to forego the use of antipyrin and similar methods, he states that he does not hesitate to place himself on record against the extreme views now given vogue. Unquestionably water, and often cold water, is the one agent of greatest utility in the management of enteric fever. Water should be used freely in every case, and should be used both internally and externally. In severe cases, or in cases that promise to be severe, if seen before the tenth day, systematic plunging in cold water should be instituted at once; and the now classic directions of Brand should be followed with reasonable strictness. The inexpert will do better by following them to the letter, than by attempting modification. The experienced will adapt his directions to circumstances. Between the tenth and twelfth days it is doubtful whether plunging should be begun. After the twelfth day the inexpert should never begin plunging. Plunging begun earlier will of course be continued or discontinued according to circumstances. When plunging is not well borne, or when for any reason it has not been instituted, frequent cold or cool sponging should be carried out. This is partly to reduce temperature, but largely, like the bathing, to promote general metabolism,

to stimulate excretion, and to keep up the tone of the peripheral vessels, which Dr. Woods Hutchinson so aptly calls "the skin heart."

The temperature index may serve as a guide to sponging as to bathing. When the temperature in the mouth does not exceed 103° F., the patient may be sponged every second or third hour with water at a temperature of 70° F., which may, if necessary, be gradually reduced to 50° F., in the course of ten to twenty minutes. When the temperature exceeds 103° F., sponging must be done at least every second hour, and the temperature of the water be correspondingly lowered—60° or even 50° to begin with, and rapid reduction to 32°, being useful at times. The effects on temperature, pulse, respiration, excretion, sleep and general comfort must be the guides as to the time, temperature and other details of the application; as a rule, patients should be allowed to sleep undisturbed for about four hours, even when applications are being made every second hour during wakefulness.

To reduce temperature, should this be thought necessary, and to prevent or control tympanites or hemorrhage, the continuous application of ice to the abdomen—usually over the right iliac fossa—is useful. Sometimes it is advisable to intermit the use of ice, or to alternate the application of ice to the head and abdomen. In cases of severe nervous and cerebral symptoms or very high temperature, there may be continuous application of ice to both head and abdomen. McCormick has had excellent success with the use of guaiacol externally.

The patient should be encouraged to drink cool water freely and frequently. The temperature should be that found to be most refreshing. Ice water should not be used.

Internal medication is useful. The bowels should be cleansed by enema on admission (unless after the tenth day), after which, according to circumstances, a few small doses or one large dose of calomel should be given. After the "calomel stool," intestinal disinfectants may be usefully employed. These may not kill Eberth's bacillus, nor neutralize its toxins, nor chase after it into the spleen or cerebrum; but they do render the patient's intestine a less favorable breeding ground for this organism and its many named and unnamed congeners; they do diminish the formation and hence the absorption of various named and unnamed toxins; they do render the course of the case less severe.

During the second week strychnine is useful in small doses, say  $\frac{1}{100}$  to  $\frac{1}{80}$  grain every second to sixth hour. During the third week it may be increased to  $\frac{1}{60}$  grain every third hour, if need be. Alcohol is rarely necessary before the third week, and often unnecessary throughout. In case of high fever, however, it sometimes saves combustion of tissue, and when the Brand system is carried out a little red wine ( $1\frac{1}{2}$  ounces) should be given before and after each bath.

Concerning complications the writer refers to hemorrhage only. He believes opium to be our best remedy. With this, continuous application of cold to the abdomen by means of the ice-bag and the use of turpentine may be combined. Ergot is useless. Calcium chloride may possibly be useful. The writer thinks it has been useful in his hands, but he has also seen it fail to do any good. McCormick advises strongly against the use of opium in hemorrhage, and warmly advocates flushing of the colon with cold water. His results have been good, but he hesitates to abandon the classic plan, which has hitherto yielded good results in his own practise.

---

#### USE DIPHTHERIA ANTITOXIN PROMPTLY AND BOLDLY.

The *Philadelphia Polyclinic* has from time to time given what is deemed conservative advice in regard to the employment of antitoxic serum in the treatment of diphtheria. While viewing the new treatment favorably, it urged caution at first in the selection of cases, until the dangers and limitations of the remedy were known. It then, as evidence accumulated, pronounced in favor of the early and sufficient administration of the antitoxin in cases of determinate diagnosis. As the result of increasing experience and observation, as well as from study of published reports, it is now prepared to occupy and defend the most advanced position, namely, that without waiting for bacteriologic confirmation of diagnosis, every patient who presents clinical evidence of diphtheria should at once receive a "curative dose" of serum, and all children of the household should be immunized by the same agent. Adults should be immunized if likely to be much exposed, and may be immunized, if they desire it, even if not specially exposed.

Of drugs of this class, one may use guaiacol or its combinations, of which the writer prefers the carbonate; phenyl salicylate (salol); betanaphthol or its benzoyl compound (ben-

zonaphthol); creosote or its carbonate (creosotal); carbolic acid and iodine; and the like. The writer usually employs salol or guaiacol carbonate, in doses of about five grains every second to fourth hour; more recently he has used benzonaphthol in doses of ten or fifteen grains. If diarrhea is troublesome, bismuth salicylate may be used with the more powerful antiseptic. If constipation be a feature of the case, an enema should be used every forty-eight hours, except during the period when ulceration is at its height, say from the twelfth to the sixteenth day, when the bowel should be let alone.

If, notwithstanding the free use of water, the urine is not excreted in sufficient quantity (that is, if it be less than thirty ounces in a day) some mild diuretic, as solution of ammonium acetate, or sweet spirit of niter, or infusion of buchu, should be given. This is rarely necessary, as the water drunk is usually an efficient diuretic, and the stimulation of the skin likewise assists excretion.

When the tongue is dry, harsh, fissured, covered with brownish fur, turpentine is useful beyond doubt. Sufficient must be given, about fifteen drops in emulsion or syrup of acacia, every second to fourth hour. If any sign of renal irritation develops, turpentine must be abandoned. Cohen has, however, never seen it do harm, and has seen it do good too often to be laughed out of its use. It also serves well in cases of tympanites or hemorrhage.

It is important to have a good syringe. It is of the highest importance to have a trustworthy serum, of as high potency as possible, so that a dose small in bulk shall be large in antitoxic units. The serums made by certain American houses are fully equal to the imported preparations, if, indeed, they are not superior. They are, in addition, more readily obtained and are likely to be more recent. No preparation that is not standardized should be employed, unless it is the only one available; and in every case the higher the number of antitoxic units per cubic centimeter the easier it is to give an efficient dose.

The failures that occurred in the early days of serum therapy in diphtheria are to be attributed to tardy and half-hearted employment of the remedy, to insufficient dosage, and to the low potency of the commercial serums, requiring a bulky injection, difficult and painful to administer.

For a child of three years, the initial dose in a tonsillar case of moderate severity seen early should be 1000 to 1500 units; in nasal

or laryngeal cases, or in cases in which the lower pharynx is invaded, or severe cases of any variety, the dose should be 2000 units; and in any case first seen as late as the fourth day, the dose should be 2000 to 3000 units. The injection should be repeated in from twelve to twenty-four hours, according to circumstances. For immunizing, 500 units should be the dose; or if infection and incubation be suspected, the curative dose of 1000 units should be given at once.

With antitoxin properly and promptly used, the throat being kept clean by applications not too frequently repeated—of which Loeffler's solution (toluol and ferric chloride) is said by competent observers to be the best—pharyngeal diphtheria is robbed of the greater part of its terrors; while intubation in laryngeal diphtheria has a far more favorable prognosis, the deaths now being fewer than were the recoveries previous to the introduction of antitoxin. What is needed, however, is promptness and courage in the use of the remedy. If *The Polyclinic* has by its former caution contributed in any degree to the hesitation with which some members of the profession resort to the use of antitoxin, we trust that this article will make amends and inspire the doubters with decision and boldness.—*The Polyclinic*, Dec. 11, 1897.

#### THE ERYSIPELAS-TOXIN TREATMENT OF SARCOMA.

The editorial department of the *New York Medical Journal* of December 4, 1897, tells us that it is evident the last word was not spoken on the subject of Dr. Coley's method of treating sarcoma when, some months ago, it was publicly discountenanced by the New York Surgical Society. As to any effect that the Society's decision may have had in the way of deterring surgeons from further resort to the treatment, it seems to have been felt wholly at home, for every now and then we meet with encouraging reports of trials of the method in foreign countries. The latest of these that has come to our notice was made by Mr. Mansell Moullin at a meeting of the Medical Society of London held on November 8, a report of which is published in the *British Medical Journal* of November 13.

Mr. Moullin showed two patients on whom he had employed the treatment for tumors suspected to be sarcomatous. One was a man twenty-eight years old, who was admitted into a hospital in November, 1895, with

a swelling in the groin of four weeks' standing. It occupied the right iliac fossa and dipped deep on the inner surface of the pubic bone. It was firm, not fluctuating, rather tender, and situated beneath the iliac vessels. Near it there were four enlarged glands. The patient appeared ill, and his temperature is described as having been irregular. On December 4 half a minim of Coley's fluid was injected, and the next morning the man's temperature had gone up to 100.8° F. That afternoon an injection of a minim was given, but without result. On the 6th and 7th, in the evening, the temperature was 102°. After that the injections were given every second or third day, and the amount of fluid injected at a time was increased gradually to six minims. Some of them were followed by rigors, and others were not. The treatment was continued until the end of February, when it had ceased to have any effect. Mr. Moullin thinks it proved beneficial, for the man's weight rose from a hundred and thirty-eight to a hundred and forty-five pounds. At first the tumor increased rapidly in size, and the skin over it grew red and tender; but about the middle of January it was noticed that the tumor was smaller and that the enlarged glands were less noticeable. At the end of the month it became larger again, and had all the appearances of being acutely inflamed. By the beginning of March it had shrunk and grown hard and irregular in outline, and there was very little of it to be felt. Since that time, for a period of twenty months, there had been hardly any change in it.

The other patient was a man forty-eight years old, who was admitted on November 10, 1896, with an abdominal tumor which is described as a large irregular swelling, elastic, hard, not fluctuating, not connected with the skin or muscles, and occupying the left flank. It descended into the iliac fossa below and extended under the false ribs above, while in front it reached nearly to the middle line. There was no glandular enlargement or pain. The tumor increased rapidly in size. On December 14 half a minim of Coley's fluid was injected, and the man's temperature rose to 100°. The injections were given every two or three days, and the amount injected was increased gradually to six minims. On the 19th there was a rigor after an injection of four minims. On January 24 there was another rigor after an injection of seven minims, and the temperature rose to 103.6° the next day. It was above normal for a fort-

night, and no further injections were given. The account of the case concludes as follows: "The tumor continued to grow until it pressed upon the colon and threatened obstruction. In January it became acutely inflamed, but this subsided, and the tumor began to shrink until it could scarcely be felt. The patient left the hospital in March stouter and stronger than on admission."

Mr. Moullin conceded that it was impossible to be sure that these tumors were sarcomatous, but he declared that he himself had no doubt of it and said it was difficult to imagine what else they could be. Certainly, he added, they were not gummata, and there was nothing to suggest an inflammatory origin. He conceded also that the use of the remedy was attended with some danger, and stated that another patient of his, who was in a weak condition, had died shortly after the second injection. He said he had employed the treatment in nine cases of sarcoma, and one death had occurred. One patient had declined further treatment after two or three injections, and two patients were still under treatment. In three cases the growths had disappeared, and in the others, although the tumors had not disappeared, they had become greatly modified and had diminished in size for a time. He confessed he was unable to decide whether the fluid acted as a specific or merely by provoking inflammation. He recalled that Dr. Coley had published accounts of twenty cases, well authenticated, in which the tumors had disappeared and the patients had remained free from recurrence.

Mr. Watson Cheyne, who remarked that Dr. Coley's statements could be relied upon implicitly, said that he had employed the method in two cases, in one of which the growth had been recognized to be sarcomatous. He called attention to the fact that in all Dr. Coley's cases the tumors had been of the spindle-celled variety. Dr. Colman alluded to the results of the post-mortem examinations of two persons who, after having been subjected to the treatment, had died of some intercurrent disease. In one there had been found a large area of softening in the interior of the tumor, and in the other cicatrices had been found which probably marked the site of past inflammation. Mr. Moullin said he had never had an opportunity of examining a tumor after the treatment, but in a case that was still under his observation a central soft portion had sloughed out since the injections had been begun, without hemorrhage from subjacent vessels.

In view of all that has been published in the United States and other countries concerning Dr. Coley's method of treating sarcoma, we are probably not warranted in supposing that, even with any modifications of it that may hereafter be devised, it will be accepted finally as the most trustworthy, for the great strides made in the antitoxin treatment of disease during the last few years justify, we think, the hope and expectation that the bacteriologist will yet provide us with a remedy so efficient that it will cease to be thought of any consequence whether a malignant growth is susceptible of excision or not. Still, as constituting perhaps the best treatment thus far proposed for cases of sarcoma in which the removal of the tumor would be too perilous, the erysipelas-toxin treatment deserves, we are inclined to think, much further trial pending the discovery of such a remedy as we have alluded to. At all events, taking into account the favorable impression it has made on some well known surgeons in France and England, we trust it will not be dropped summarily in the land of its originator.

#### THE TREATMENT OF ABORTION.

In an interesting letter to the editor of the *Medical News* under date of November 20, 1897 (*Medical News*, Nov. 27, 1897), Dr. PAUL F. MUNDE tells us that he has read with interest a recent article on "The Treatment of Abortion" and begs to be allowed to offer several criticisms:

1. The author very properly pronounces Thomas' small dull-wire curette as useless for the purpose of emptying the uterus during an abortion, and declares his (Thomas') "large dull-wire curette, with an opening admitting the tip of a forefinger, an admirable instrument for the purpose, formidable as it appears."

Munde thinks the author is in error in calling Thomas' large dull-wire curette a "formidable instrument." The only two dull-wire curettes which go by the name of Dr. Thomas are the small one, which is used for removing intra-uterine vegetations and is useless in abortion, and a somewhat larger one, which he has employed for years in abortions under two months, where others use Recamier's or Sims' curette or Simon's sharp spoon. Munde has never found it necessary to employ a sharp curette in early abortions, or even later, unless there had been an acute endometritis with inflammatory adhesion of the placenta.

The curette which the author calls a "formidable instrument" can be no other than the large dull curette, attached to a long, stout shank and handle, which Munde first introduced to the profession in 1883 (see *American Journal of Obstetrics*, February, 1883) in an article on "The Immediate Removal of the Secundines after Abortion" (and which is mentioned and pictured again in his "Report of the Gynecological Service of Mt. Sinai Hospital," *American Journal of Obstetrics*, October, November, and December, 1895), and has been sold by instrument-makers under Munde's name for years.

There are two shapes of Munde's placental curette, one round and the other oval, the latter being especially designed for use when the cervical canal is long and not fully dilated. After the second month both can usually be inserted without difficulty through a fully dilated canal. A large flat forceps for the removal of the detached decidua accompanies the curettes. The curettes may be used whenever the canal is sufficiently dilated to admit the index-finger.

2. The author criticized fails to lay down, as a condition indispensable and invariable for the efficient and thorough use of the curette after abortion, that the uterine canal should be sufficiently dilated to permit the index-finger to explore the uterine cavity to the fundus, in order not only to determine the quantity and location of the retained secundines, but also to enable the operator to be perfectly sure that the cavity has been entirely emptied when the operation is completed.

To trust to the information on this point imparted by the curette alone, even in the hands of the most expert operator, is notoriously unsafe.

3. The same author has omitted to mention that at times great assistance is afforded to the cervical dilators which he mentions by gently nicking the lips of both the external and internal os with a straight, blunt-pointed knife, especially when the edges of the external os are rigid and cicatricial as occasionally happens after a trachelorrhaphy.

Munde has found the index-finger, assisted by counter-pressure over the fundus with the other hand, as good a dilator as any of the cones or olives, provided it was possible to insert its tip ever so little into the internal os. In incomplete abortion, when any considerable portion of the secundines is retained this can usually be easily done.

4. Munde cannot agree with this author's

advice and practise to tampon either the uterus or vagina after emptying the former of the products of conception. An empty uterus after abortion always contracts, and all hemorrhage from its cavity ceases. A failure to contract at that time is an exception. To pack the uterus is therefore unnecessary, and rather tends to interfere with contraction and involution than to aid them. And why pack the vagina? He usually employs a hot sterilized or carbolized intra-uterine douche after emptying an aborting uterus, and he can scarcely recollect a case where prompt contraction and cessation of bleeding did not take place. Only in a woman very much exhausted from hemorrhage might it be advisable to pack the empty uterus after abortion with iodoform gauze, or better sterilized gauze, in order to save her even the few drops of blood which would ooze away during the first day or two, until she has rallied. At least this is Munde's opinion, and has been his practise for many years, and he has no reason to regret or change it. Of course, if the object of packing the uterus is to influence a septic condition of the endometrium, the case is different. But then it would seem to him that gauze soaked in peroxide of hydrogen, or kept moist with the forty-per-cent. dilution of alcohol recently recommended by Dr. Ill, must be preferable to iodoform gauze as a uterine packing.

#### ANESTHETICS.

In the *British Medical Journal* of November 20, 1897, WALLER contributes an important paper on anesthetics. His opinion is altogether adverse to chloroform, and he believes chloroform is seven times as powerful as ether, and therefore more dangerous. He is greatly astonished that in the face of the clinical experience of the past fifty years chloroform should still be frequently employed in minor surgery, though he is well aware of the superior convenience of chloroform over ether, and that there are cases and circumstances rendering its use justifiably preferable to that of ether. But he believes that the proportion of such cases is very small in comparison with the actual number of cases in which it is habitually employed.

With regard to ether, Waller thinks an exaggerated estimate has been given of the inconvenience of administration, of the physiological counter-indications, and of the pathological after-effects.

With reference to the admittedly large

number of deaths by chloroform, there seems to be no escape from the two horns of a dilemma. Such deaths are the result (a) of an agent dangerous under all circumstances, or (b) of an agent dangerous only when unskillfully administered.

(a) If chloroform is dangerous under all circumstances, it may not be employed in minor surgery. Death in this class of cases is therefore unjustifiable, and should be considered as a criminal offense.

(b) If chloroform is dangerous only when unskillfully administered, then again death by chloroform is unjustifiable, and ought to be considered as a criminal offense.

There can be no escape from one or other of these two alternatives. There have been deaths due to careless or to unskilled administration; there have also been deaths in skilled and careful hands. But unless we are to admit that chloroform is a "safe" anesthetic, and any death the result of carelessness or ignorance, we must admit that chloroform, being a potent reagent, is, *ipso facto*, a "dangerous" reagent, to be used only on serious grounds, and not to be employed as a routine drug in all kinds of cases, simply on account of its superior convenience.

#### THE RELATIVE EFFICIENCY OF VARIOUS ANESTHETICS.

The *British Medical Journal* of November 20, 1897, speaks editorially of Waller's paper on anesthetics in which he discusses the relative advantages of ether and chloroform. Dr. Waller's experiments have convinced him that the most satisfactory way of testing the efficiency of anesthetics is to employ freshly prepared nerves, and to cause them to respond to electrical stimuli while subjected to various narcotizing vapors. The method is as beautiful as it is original. Not only is he enabled thus to investigate the anesthesia produced, or, as he terms it, "temporary immobilization," but to ascertain the strength of vapor which kills the nerve and produces "permanent immobilization." Under ordinary physiological conditions the galvanometer reveals the presence of currents in the nerves. The action of narcotics is to send the nerve to sleep, and the absence of the current is proof positive of this anesthetic sleep. Remove the vapor and the nerve recovers itself, and again the nerve currents appear. Now, by testing a number of substances, Dr. Waller has found that while all those which produce anesthesia also

bring about death of the nerve, some are far more deadly than others. Richardson, in his lectures on narcotic vapors, was disposed to regard the chemical and physical properties of narcotics as affording no criteria of their power as anesthetics, but his methods lacked the precision of those now under consideration. The heart is capricious because it is a compound organ with a nerve factor, a muscular factor, and a nerve-cell factor. Dealing with isolated nerve the problem becomes immeasurably simpler, and at the same time the experiments can be kept absolutely under test conditions.

We have hitherto been assured that chloroform killed either by paralyzing respiration through the nervous system, leaving the other tissues severely alone, or brought about death through circulatory failure, due, it may be, to vasomotor dilatation, or through incapacitating the heart. Now we learn that not only does chloroform destroy muscular tissue and narcotize the nervous centers through its influence on the blood, but actually attacks nerve fibrillæ, and destroys their irritability. It is a matter of indifference to "the man in the street," as Dr. Waller points out, whether he is killed through his heart failing or by asphyxia; what interests him most is how he can be saved pain with as little chance of losing his life as his surgeon can conveniently arrange. From this point of view it is somewhat startling to find that dose for dose chloroform is seven times more deadly than ether when tried upon the isolated nerve—that is, upon a highly specialized protoplasm. And what appeals most to the practical man is that these figures show how narrow a margin in the case of chloroform there is between a non-lethal and a lethal dose, while seven times that margin exists when ether is in use. The specific action of nitrous oxide has been asserted by some, but denied by Wood and Cerna and the late Sir George Johnson. Dr. Kemp's careful study confirms the former view, but according to Dr. Waller it is an anesthetic which has little or no action on nervous tissue. Carbonic dioxide, which Snow and Richardson lauded as an anesthetic, is, Dr. Waller finds, a powerful agent to produce "immobilization," thus confirming the assumption of the older observers. But a fact of extreme interest, because unless carefully explained liable to fatal misunderstanding, is Dr. Waller's observation that the presence of carbon dioxide favors anesthesia and lessens its risk. The combination of chloroform and carbonic oxide is not, it must

be distinctly understood, simply chloroform given with very little air. This distinction is made very plain by Dr. Waller himself.

Accepting nerve tissue as a criterion of the vitality of the constituents of the body, these experiments are very striking, and reveal in a clearer light the profoundly powerful character of chloroform.

In the statistics of deaths under these two anesthetics ether stands better than the proportion of seven to one. The proportion in its favor is about thirteen to one; but, as Dr. Waller pointed out, the problem of the action of narcotics on the whole organism, although exemplified tersely by a nerve experiment, is in itself far more complex. It is often stated that the after-effects of ether are far more fatal than those due to chloroform; but no foundation in experiment or statistics exists to prove this, and, as Dr. Waller cogently puts it, the use of chloroform, if it be dangerous under all circumstances, is, unless under exceptional circumstances, unjustifiable; and if it is only dangerous when unskilfully given, its deaths amount to homicide. This is Dr. Waller's chloroform dilemma.

The discussion, in which Professor Richet, Dr. Lawrie, Dr. Shore, Professor Gaskell and Professor Stewart took part, turned mainly upon the oft-debated evidence afforded by cross-circulation experiments, as to whether or not the fall of blood-pressure incident to chloroform narcosis is brought about through depression of the vasomotor center or through weakening of the heart itself. How far such experiments can be accepted as conclusive remains to be seen in the face of so much evidence which has now been accumulated by the researches of MacWilliam, Hare and Thornton, Leonard Hill, and others; it is difficult to exclude the vasomotor center as in some way causative of the fall of blood-pressure under chloroform. The practical fact which stands out in terrible distinction is that deaths under chloroform have not lessened in spite of physiology or Hyderabad Commissions. It is useless to contend that these deaths arise because the physiologists teach dangerous tenets, since the large percentage of persons who give chloroform know little of and probably care less for physiology. It is rather the careless and the overconfident in whose hands such accidents happen, while as a rule it is safer in those of persons who have leisure and training to follow the trend of modern thought and teaching concerning anesthetics.

### THE TREATMENT OF ATROPHIC RHINITIS.

CASSELBERRY, the well known rhinologist of Chicago, writes on atrophic rhinitis in the *New York Medical Journal* of November 20, 1897. He asserts that in looking over the literature of this subject somewhat, we will find that although many drugs have been employed in the treatment of atrophic rhinitis, yet they have nearly all been used upon the general principle of producing what is called by some "stimulation," by others "irritation." These two terms are alike in kind, differing only in degree.

We find that the German school, clinging as usual to their belief that this disease, like all others, is caused by the presence of unusual kinds of bacilli or bacteria in unusual numbers, advocate the use of solutions of bichloride. Koch tells of the great benefit and complete cure in some cases of atrophic rhinitis by the use of a spray of 1 to 4000 bichloride.

Löwenberg always uses antiseptic douches of mercuric bichloride (1 to 4000), having first removed the crusts with warm saline solution.

Thost applies bichloride of mercury in a solution of 1 to 2000 with a camel's-hair brush twice a day. He remarks that this treatment has been in vogue for a number of years and has always produced good results.

Of the Italian school, Cardone (professor at the University at Naples), believing that atrophic changes in the nose are similar to the process of pneumonia and dependent upon the same bacilli, uses the bichloride in a solution of 1 to 2000, giving internally iron and cod-liver oil; and Marano bases the same treatment upon the same belief.

One of our fellows, Dr. Mackenzie, of Baltimore, has made use of a solution of mercury bichloride, two grains to a pint of water, by atomization, and recommends the same as a gargle and nasal wash.

Belfanti says that having used with great benefit the diphtheria antitoxin in ozena, he employed it also in atrophic rhinitis, and to his great astonishment obtained very favorable results. He has not as yet tried the treatment long enough to publish his cases.

Electricity, so highly commended by some physicians, has been used largely by Dr. Shurley, who in 1880 was the first to recommend it, and the treatment has been used to quite a large extent by others. The application of the positive pole of the galvanic current to the back of the neck and the negative

pole to the nostrils to produce stimulation has been the usual method employed by Drs. Shurley, Delavan, Hartman, and others. The exact technique can be found in the Transactions of the American Laryngological Association. Even the faradic current has been used and recommended; also the use of copper electrodes on the principle of electrolysis.

Another method of treatment is that recommended by Gottstein, by which the nasal mucous membrane is stimulated or irritated by the introduction of absorbent cotton into the nostrils, or some form of medicated wool, as recommended by Woakes.

Among the various drugs which have been employed in this way are iodoform, iodol, aristol, salicylic acid, camphor, iodine, perchloride of iron, tannin, alum, rhatany, and opium. Medicated bougies, manufactured with a basis of gelatin and glycerin and medicated with the drugs just mentioned, have been used a good deal in atrophic rhinitis, and this method by which drugs can be kept in contact with the mucous membrane for a long time seems to be a reasonable one. The inhalation of stimulating volatile substances obtained from the essential oils and from cubebs, tar, eucalyptus and thymol has also been largely employed; and we find in the shops a number of varieties of so-called autoinsufflators, by means of which the patient is enabled to blow into his own nostrils the fumes of carbolic acid, menthol, oil of pine, etc.

A somewhat different plan of treatment, but intended to produce proper stimulation and secretion, is called "massage" of the mucous membrane. Laher, of Vienna, says that this method of treatment has given most satisfactory results. The method is employed by wrapping cotton around a probang introduced against the atrophic mucous surface and held in position by the left hand, while regular motion is made by vibrating the left arm with the right hand. The writer states that after a few days normal secretion is established and the crusts become thinner and fewer in number. He believes that this method of treatment will recommend itself very highly to anybody using it.

Demme has found that massage performed after the manner described is made still more efficacious by using a twenty-per-cent. solution of pyoktanin in lanolin. He has succeeded, he says, in every case. Garnault and others have used massage by means of electrical vibrations.

It seems to the author that the use of destructive agents in the treatment of this disease deserves mention only to be censured. It is possible that an obstinate ulceration will require to be cauterized, but it seems a very useless procedure to recommend the galvano-cautery and chromic acid where their use can be indicated only in rare instances, and then should be employed in the most judicious way. If the middle turbinated body needs to be reduced in size or a deflected septum is too prominent, as may be the case in atrophic rhinitis, cutting instruments will accomplish the result desired in a much more reasonable way. We cannot afford to still further devitalize an atrophic septum with a heated electrode.

Many articles have been written on atrophic rhinitis where nothing more is offered in the way of treatment than the spraying of solutions of borax in glycerin, ammonium chloride in glycerin, solutions of chlorate of potassium and of phosphate of sodium and phosphate of ammonium, snuffs of animal or wood charcoal, compounds of honey and terebene, and ointments of creosote. Mather thinks it important to combine opium with his saline douches, and if irritation and headache are produced by the nasal wash, recommends the smoking of a cubeb cigarette.

Struebing affirms that he has used every medication that has ever been recommended, and he has arrived at the conclusion that the nose should be cleaned by instruments because douching is harmful to the ears, and that the only successful plan of treatment is the use of bougies medicated with creolin, or better still, metacresolaristol in one-per-cent. aqueous solution.

Wendell Phillips recommends an antiseptic solution called baptoline, and also one of acetotartrate of aluminum in water, half a drachm to the ounce.

Several drugs have been employed which deserve rather more attention. One of these is resorcin. Masini, as far back as 1882, was using one-half of one per cent. of resorcin combined with vaselin, applied with the brush. He says the treatment is an ideal one. Other practitioners have used it in solution, and it has been employed quite generally in New York, though the results obtained by its use have not fulfilled expectations.

The use of hydrogen peroxide seemed for a time to promise great amelioration in this disease, and as a germicide and disinfectant

its ability is unquestioned. It is, however, a rather troublesome medication to employ, and in the writer's hands, while it produces cleanliness, is not a useful stimulant, but leaves the mucous membrane quite as dry as ever. In anything like strong solution he has found it quite irritating and apt to produce a sub-acute nasopharyngeal catarrh.

Professor Cozzolino, writing in 1887, says that after cleansing the nostrils, either absolute or diluted ethyl alcohol ( $C_2H_5OH$ ) should be applied on small sponges or on pieces of absorbent cotton. He considers this application as one of the best antiseptics and fulfilling in a remarkable degree the properties of stimulation to the mucous surface of the nose. He used ozone for a time and with some benefit, but the apparatus is complicated, and such remedies are apt to fall into disuse.

#### HOLOCAINE VS. COCAINE.

The *Journal of the American Medical Association* of November 13, 1897, contains an article upon holocaine by the well known ophthalmologist, Dr. Hotz. He tells us that he first tried it on a few normal eyes and on eyes with foreign bodies in the cornea, with the following results: The instillation always caused more or less smarting and burning, which, however, lasted but about half a minute; it also produced considerable redness of the conjunctiva (palpebral and ocular), which persisted during the whole period of anesthesia. Within one and one-half to two minutes complete anesthesia of the cornea was noted; after six minutes the sensibility of the cornea began to return, but a second instillation prolonged the anesthesia for another five minutes; and if then another drop was instilled the anesthesia could again be continued. It would seem, then, that the anesthetic effect of holocaine can be kept up indefinitely by repeating the instillation every five minutes. With cocaine this cannot be done; at least the writer has noticed that if the eye is coming out of the cocaine anesthesia, repeated instillations do not restore the anesthesia; on the contrary, he has often found the eye becoming more sensitive the more cocaine was used. Holocaine does not contract the conjunctival blood-vessels, and therefore causes neither bleaching of the eye nor lessening of the lacrimal secretion nor drying of the corneal epithelium. It does not dilate the pupil and has no effect on the accommodation. On account of these

qualities one would naturally feel inclined to use this new anesthetic in preference to cocaine in all operations on the eye. But a series of comparative tests of the efficiency of the two remedies seemed to show that the anesthetizing effect of cocaine (two-per-cent.) is more thorough and penetrating than that of holocaine (one-per-cent.). The writer had, for instance, two patients with corneal ulcers which required the repeated application of the electro-cautery. He made one application under holocaine anesthesia and the next time cauterized the same eye under cocaine. Both patients, who thought cocaine was used on both occasions, said the first cauterization was decidedly painful, while they did not feel the second one at all. The writer performed an advancement of the externus on the right eye under holocaine and on the left eye of the same patient under cocaine. Complete anesthesia of the conjunctiva was present in both eyes; but the cutting and suturing of the tendon was decidedly painful in the holocainized eye, while scarcely felt in the cocaineized eye.

The most telling illustration of the difference in their penetrating effect was furnished by a case of subconjunctival injections of cyanide of mercury. Several injections had previously been made under cocaine, and the pain following the injections was moderate and never lasted over five to ten minutes. The next injection was made under holocaine and caused the most violent pain, which after twenty minutes showed no sign of letting up in intensity; he then instilled cocaine, and within five minutes the patient was free from pain. One week later this experiment was repeated with the same result.

All these observations seem to show that the effect of holocaine is very quick, but superficial; it is therefore a very useful local anesthetic for the removal of foreign bodies from the cornea, and for operations upon the conjunctiva; but for deeper operations, and especially for those which involve the opening of the globe (iridectomy and cataract extraction), he regards cocaine as the more reliable anesthetic.

---

*THE PHYSIOLOGY AND THERAPEUTICS  
OF THE THYROID GLAND AND  
ITS CONGENERS.*

In the *Journal of the American Medical Association* of November 13, 1897, H. G. WELLS concludes a paper on this topic by the following statements:

Put in compact form, the sum total of our knowledge of the thyroid gland amounts to the following, according to the results of the latest investigations:

The thyroid gland is an organ of very variable size and shape, reaching its highest degree of development at about adult life, and decreasing with old age.

It is capable of great hypertrophy, but probably is not capable of more than a slight degree of regeneration.

Its secretion is a colloid material, which is discharged into the general blood-current by way of the lymphatics.

The colloid material contains the active material of the gland, which is a complex but very stable body, called "thyroidin," which contains about ten per cent. of iodine.

This substance either acts as an antitoxin to the products causing autointoxication, or furnishes some substance necessary to tissue metabolism.

Thyroidin is necessary to the animal economy, absence of it in adults producing myxedema; in the new-born, cretinism.

The amount of iodine in the thyroid glands of the inhabitants of any given district varies inversely with the prevalence of goitre in that district.

Thyroid glands of residents of Chicago contain fully four times as much iodine as do glands in the goitrous districts of Germany.

It is probable that glands from the Atlantic coast contain about the same amount of iodine as do the Chicago glands.

Simple parenchymatous goitres contain about the same total amount of iodine as normal glands, but the proportional amount is much smaller. Probably colloid goitres contain the same proportional amount with a very much higher total.

The amount of iodine in the glands of children, from a mere trace at birth, steadily increases until adult years. It then decreases, and in old people again becomes very small.

Therapeutically the thyroid extract is a specific in cretinism and myxedema.

In simple goitre and in obesity the majority of cases are improved or cured.

It seems to have some value in tetany, scleroderma, and arrested growth.

The value in psoriasis and other skin diseases, tuberculosis, insanity, rickets, etc., is doubtful.

It is contraindicated in exophthalmic goi-

tre, heart lesions, albuminuria, and glycosuria. The dose should never be so large as to produce symptoms.

#### *SOME DETAILS IN THE TREATMENT OF PHTHISIS.*

Under this title CROOKSHANK in a lecture reported in the *Clinical Journal* of December 15, 1897, speaks in an interesting way of the treatment of this ever present disease. As he well says, a common but very troublesome occurrence in phthisis is vomiting induced by cough after meals. Nothing relieves this so well as the prescription of:

Liquor strychninæ,  $\mathfrak{m}$  v;  
Bismuth. subnitrat., gr. xx;  
Mucilag. tragacanth., 3 ss;  
Aquæ, ad f 3 j.

To be taken four times a day.

Other varieties of dyspepsia met with are those complicated by diarrhea. If the diarrhea be, as is often the case, merely lenteric, treatment is simple; but if pain and tenderness in the right iliac fossa be present, and ulceration of the bowel probable, relief is not so easily given. Rest, and usually complete rest, should be enforced, although it must always be borne in mind that, if tubercular diarrhea be suddenly checked and the patient confined to bed, the pulmonary disease will make rapid progress. If the pain and tenderness be marked, the right iliac fossa had better be freely painted with tincture of iodine until the skin be broken.

A comfortable pad of gamgee tissue should be worn on the abdomen so as to keep up gentle pressure. The use of cod-liver oil, cinchona or malt should be stopped at once, and the diet modified, so that milk (plain or flavored with rum), kumiss, arrowroot, corn-flour, and Benger's or Mellin's food may form the staple. Solid food, except for a little pounded fish or chicken, is better withheld.

Bismuth is undoubtedly the best drug to give, and its most suitable salts the subnitrate, salicylate, or subgallate, prescribed thus:

Bismuth. salicyl., gr. xx;  
Tinc. opii camphorat.,  $\mathfrak{m}$  xx;  
Mucilag. tragacanth., f 3 ss;  
Aquæ camphoræ, q. s. ad f 3 j.

To be taken every four hours if necessary.

If this does not check the diarrhea, fifteen minims of tincture of coto should be added to each dose, or half a grain of cotoin given several times a day in pill. These measures failing, it becomes necessary to give opium

in some combination or other, the most potent being that recommended by Dr. Fowler:

Cupri sulph., gr.  $\frac{1}{4}$ ;  
Pulv. opii, gr.  $\frac{1}{4}$ ;  
Ext. gentian, gr. ij.

Make into one pill and give one two or three times a day.

The pill certainly checks the diarrhea very rapidly, but has a tendency to furl the tongue and set up nausea. It is of most use when given occasionally during the continued administration of bismuth.

The relief of constipation is, of course, as important in phthisis as in any other condition. Mercurials and all cathartics are unsuitable; the best preparations are the German licorice powder, the confections of senna and sulphur, mild aloes and belladonna pills, and the combinations of cascara sagrada. They should be given in small doses twice or thrice a day after meals; and not in one large dose at bedtime. If this plan be followed, the dose can be gradually reduced, and the constipation cured and not merely relieved. The following recipe is useful:

Tinc. nucis vomicæ,  
Spt. ammon. aromat.,  
Tinc. belladonnæ,  
Spirit. chloroformi,  
Extract cascara sagrada, fluid, of each equal parts.  
Fifteen to thirty drops in water thrice daily after meals.

It is of the greatest importance to carefully examine the teeth in all cases of phthisis, real or suspected. Many cases of indigestion depending on carious teeth have been diagnosed as early phthisis, the suppuration having been free enough to set up mild symptoms of septic absorption, and the mimicry completed by lenteric diarrhea due to the imperfectly masticated food. But in all cases of undoubted phthisis no effort should be spared to have carious stumps extracted, the gums cleansed, and artificial teeth supplied. It is worth noting how few phthisical patients are the possessors of good teeth. As soon as the digestive system has been brought into good order we have to make a choice between certain drugs, valuable both for their general action and their special effect on certain symptoms. The first and best of these is, of course, cod-liver oil. In some cases it cannot be taken; it should be tried in all. It is best given in drachm doses, twice a day, ten minutes after food, and it is best taken from a tumbler between two strata of fresh lemon juice. The dose may be increased if the oil is well borne, though little advantage is gained by heroic dosage, any quantity much above an ounce

daily being passed unabsorbed. And no amount of cod-liver oil that can be absorbed will compensate for a destroyed appetite and nauseated stomach.

The exhibition of gentian and sodium bicarbonate may be continued with advantage while cod-liver oil is given; and should the lemon juice be not acceptable to the patient, the following may be tried:

Ether, f 3 ij;  
Cod-liver oil, f 3 v.

Dose, two teaspoonfuls.

A third and very excellent method is to give the oil in small doses combined with one of certain acid mixtures. The whole then forms what Dr. Williams has called an oil sauce. One of the best of these mixtures is made up thus:

Acid. nitrici dil., ℥ xv;  
Decoction. cinchonæ, f 3 j.

It sometimes sets up diarrhea, however, and if so one may try:

Liquor strychninæ, ℥ v;  
Acid. phosphor. dil., ℥ xv;  
Infus. quassia, f 3 j.

A third formula is:

Acid. sulphur. dil., ℥ xij;  
Tinc. aurant., f 3 ss;  
Salicin, gr. iij;  
Syr. zingib., 3 ss;  
Infus. aurant., f 3 ss.

Many more will be found in Dr. Williams' book.

These mixtures are excellent in themselves, and form very palatable combinations with the oil. They should be dispensed separately from the oil, and the "oil sauce" only mixed at the time of taking.

Half a drachm of cod-liver oil, five minims of compound tincture of gentian, and twenty-five minims of lime-water make an excellent emulsion for the use of children. Every effort should be made to induce the patient to take cod-liver oil, but it sometimes is obstinately rejected. In that case it is better to fall back on the general tonics than to employ any of the so-called substitutes for cod-liver oil; they are all unsatisfactory. Malt has some diastatic value, but often sets up diarrhea, and the latest suggestion—petroleum—has nothing but novelty to recommend it. As a general tonic few mixtures have a higher value than that of nitric acid and cinchona, just mentioned. It is particularly suitable to chronic cases with good digestive powers. Arsenic is of the highest value, especially in cases marked by anemia and tremor. It frequently controls night sweats,

and it is an old clinical observation that if the patient be tired in the forenoon arsenic is indicated. A most convenient way of giving it is as the arsenate of iron, one-eighth grain in pill three times a day. The liquid preparations of iron are badly borne by all tuberculous patients, and do less good than might be expected.

Quinine, although it has little permanent effect on the pyrexia, is best suited to cases with irregular fever. It can be given in five grain doses thrice daily, either in cachet or dissolved in lemon juice with fifteen grains of ammonium carbonate in water, so as to form an effervescing mixture. But the most pleasant way of all is that generally employed in the East, of solution in aromatic sulphuric acid. The combination of two grains of quinine with one of digitalis, to form a pill, is excellent in cases with a small, frequent, and low tension pulse. This pill is, of course, Niemeyer's famous combination, but with the opium omitted, as is best, unless diarrhea be troublesome and depression great. Three or four of these pills may be given every day.

One other drug—guaiacol—is deserving of special mention. Creosote in capsules or dissolved in cod-liver oil is good, but guaiacol is better, and less likely to irritate. Guaiacol carbonate is an agreeable form, of which as much as a drachm can be given daily; but the best formula is:

Guaiacol, ℥ ij-xx;  
Rectified spirit, f 3 ss;  
Water, f 3 ss.

This mixture can be given two or three times a day after food, and seldom disagrees if care be taken to begin with small doses of the guaiacol, gradually increased as toleration is established. The writer has several times seen great improvement follow its use, especially in acute cases. But while these drugs of general value are being given some special symptom is sure to claim attention.

If the night sweats be not checked by acids and quinine, the first thing to be tried should be a glass of port-wine negus, given at bedtime every evening. The patient should be sponged about the same time with vinegar and water, or, if we wish to be elegant, dilute acetic acid and eau de Cologne.

The prescription that is most frequently successful is that of a pill—to be taken in the evening—composed of:

Zinci oxidi, gr. iijss;  
Extract belladon., gr. ¼;  
Extract gentianæ, q. s.

The dose of the zinc oxide and belladonna may be increased, if needed, or one-eighth grain of morphine acetate substituted for either ingredient, or a pill containing one-sixtieth grain of atropine sulphate can be given. Dr. Brunton recommends the excellent plan of giving at night liquor strychninæ combined with opium, and pills containing hyoscine, hyoscyamine, picrotoxin ( $\frac{1}{4}$  grain), agaricin ( $\frac{1}{12}$  grain), or gelsemine ( $\frac{1}{60}$  grain), sometimes succeed when other drugs have failed. Pilocarpine has been advocated, and the addition of five grains of Dover's powder to the negus is of use, even if it be not agreeable.

At the best our treatment of night sweating is unsatisfactory, and our knowledge of its ultimate pathology not much better. The current explanation scarcely explains why so many patients sweat profusely in the early stage of their disease, when fever is slight, and not in later stages when fever is marked; and the writer cannot see that the sweating of the early stage of phthisis is quite the same as that of the last stage of all.

In this last stage the hectic is as much due to the infection of the cavities by pus cocci as any other cause. In the early stage, before breaking down has commenced, it can only be due to absorbed products of the tubercle bacilli themselves. In the intermediate stages, when products of caseation are being coughed up and streptococcic infection has not yet taken place, absorption of chemical products would naturally be less. The writer is therefore inclined to regard sweating rather as a direct manifestation of toxemia than as due to the nocturnal fall of temperature. The ordinary nocturnal ebb of the body's functions would probably by itself be sufficient to determine the time of the sweating.

Cough being a reflex act designed to remove harmful matter from the air-passages, it follows that a cough checked is not always a cough well treated. But it is nearly always expedient to secure a night's rest by giving, the last thing in the day, a tincture containing morphine. Either of these formulæ will be found useful:

Liquor morphinæ acetatis,  $\mathfrak{m}$  viij;  
Ether. chlor.,  $\mathfrak{m}$  vj;  
Succi limonis,  $\mathfrak{m}$  xv;  
Mucilag. acaciæ, ad  $\mathfrak{f}$  3 j.

Dose, one drachm.

Morphinæ acetatis, gr. 1-16;  
Acid hydrocyan. dil.,  $\mathfrak{m}$  ij;  
Oxymel scillæ,  $\mathfrak{m}$  xxx;  
Aque, ad  $\mathfrak{f}$  3 j.

Unless there be a tendency to hemoptysis

it is best not to give morphine mixtures during the day, but to employ a simple preparation containing either acid and oxymel or ammonia and squill. It should be remembered that acids check, and alkalies promote, pulmonary secretion. It is best, then, to reserve the combinations of ammonia for cases with secondary bronchitis, when the following prescription may be used:

Tinc. hyoscyami,  $\mathfrak{m}$  xx;  
Spirit. chloroformi,  $\mathfrak{m}$  x;  
Misturæ ipecac. cum ammoniæ, ad q. s.  $\mathfrak{f}$  3 j.

If the sputa be very tenacious an alkaline draught, taken in warm water on first waking in the morning, will be found to loosen the secretion and prevent retching from continued cough. Such a draught may be composed of:

Sodii bicarb., gr. x;  
Sodii chlorid., gr. iij;  
Ether. chlorid.,  $\mathfrak{m}$  v;  
Aque anisi,  $\mathfrak{f}$  3 j.

One should, however, seek to reduce as much as possible the amount of medicine taken into the stomach, and in the treatment of cough there is ample opportunity for alternative methods. Nothing gratifies patients more than the simple licorice and aniseed lozenges familiarly known as the "Brompton Blacks." Equally pleasing, and of rather more benefit, is the use of Yeo's respirator on which some volatile fluid has been dropped, for half an hour several times a day. Useful formulæ are:

Ol. eucalypti, 50 parts;  
Spirit. chloroformi, 50 parts.

Ol. pini sylvestris, 50 parts;  
Spirit. vini rect., 50 parts.

Menthol, 20 parts.  
Ol. olivæ, 80 parts.

About twenty drops of any of these combinations may be used on each occasion; but as they are all stimulant and expectorant, none of them should be prescribed if hemoptysis has recently occurred.

Excellent sedative inhalations can be made by adding succus conii  $\mathfrak{f}$  3 j, tinctura lupulini  $\mathfrak{f}$  3 ij, or tinctura hyoscyami  $\mathfrak{f}$  3 j, to eight fluidounces of boiling water with a few drops of chloroform in a Maw's porcelain inhaler. However, a morphine lincture by night and a simple lozenge by day may be all that is required. But, to recapitulate: Ipecacuanha and hyoscyamus and the warm alkaline draught if there be much secondary bronchitis, sedative inhalations and acid mixtures

if there be old cavities to dry up, and stimulant inhalations and alkaline mixtures if secretion be not adequately removed, have each and all their place. Two other measures which relieve cough should not be forgotten—the vigorous painting with tincture of iodine on the chest wall over an old and irritating cavity, and friction with a stimulating liniment if much chronic pleurisy exist.

*THE TREATMENT OF PROSTATIC HYPERTROPHY BY OPERATIONS PRACTISED UPON THE ADNEXA.*

ALBARRAN and MOTZ (*Annales des Maladies des Organes Génito-Urinaires*, January, 1898), concluding a long article upon this subject, state that it is rational to admit *a priori* that castration diminishes hypertrophy of the prostate, especially when the enlargement is of the glandular form; that although the anatomico-pathological evidence is still inconclusive, clinical experience shows that there is a marked diminution of the enlargement of the prostate after castration. This diminution is due at first to relief of the congestion, later to true atrophy. This atrophy may be very slow and may not begin for six months or even more after operation, and may progress for more than two years. It may advance to such a state that the prostate may not be felt by rectal palpation. Certain portions of the enlarged organ may atrophy, and this process may affect the lobe which projects into the bladder. It is not possible to assert at present that all enlarged prostates will atrophy after castration, nor can it be said to what extent this atrophy will progress. It is even probable in certain cases there may be no atrophy. As to the effect of castration on the bladder in prostatics with dysuria without retention of urine and in whom the contractility of the bladder is preserved, patients suffering chiefly from frequency of micturition due to congestion of the prostate and bladder, the operation is followed by a rapid improvement of vesical symptoms, due undoubtedly to the relief of congestion. In prostatics suffering from retention of urine the results are truly remarkable. Of twenty cases operated on the operators state that three died, and in seventeen others spontaneous urination was rapidly reestablished. Four patients were able to urinate even a few hours after the operation. Eight others recovered this power even within the first week. In the slowest case spontaneous micturition occurred a month after operation.

In prostatics suffering from chronic, incomplete retention of urine it was found that about fifty per cent. were entirely cured and the large majority of the remainder were greatly benefited. In prostatics with chronic complete retention the mortality of the operation was large, though even among these patients more than half were cured and most of the remainder were greatly improved.

The authors find that out of 124 cases the mortality was 14.5 per cent., due in the main to antecedent infection of the kidneys. Contrasting this mortality with that of the prostatics received in the Hospital Necker and not submitted to operation the authors find that the figures stand at fourteen per cent.—*i.e.*, 31 deaths in 220 cases. Operation is in itself not grave, and the mortality could be reduced to nothing by a proper selection of cases. In certain instances feebleness and inaptitude to work have been noted after operation. All these conditions are transitory. Certain psychic disturbances, varying from simple intellectual depression to delirium or even acute mania, have been observed, but these disturbances commonly appear in the first days following operation and finally disappear without leaving any trace. In contrast to this it is worthy of note that certain cases have exhibited a decided improvement in mental condition after operation.

The authors hold that the brilliant results obtained from castration in cases of enlarged prostate are such that they fail to justify not recommending it in the majority of cases. They would, however, reject this operation in cases of renal infection, in cases where the patient is extremely ill, and in cases which can be cured by simpler means. Thus in case of acute retention the treatment advocated by Guyon will be often successful. When this fails, or when an acute retention is constantly occurring and inevitably leading to chronic retention, an operation will be indicated. Cases of chronic retention may be complete or incomplete. The operation is indicated when methodical catheterization will not cure infection. The only contraindications to catheterization would be the existence of an intravesical projecting prostatic lobe which could be removed, which would justify prostatectomy. Neither the size or the amount of induration of the prostate, nor the loss of vesical contractility, should be considered as absolute contraindications. The time to establish a clinical distinction between fibrous and glandular forms of prostatic hypertrophy is futile. The comparison of

post-mortem findings and the results of clinical examination before death have shown that soft prostates were often essentially fibrous, whilst hard prostates were distinctly glandular. Indeed, the authors hold that as the evidence now stands castration probably also favorably affects fibrous prostates.

#### TREATMENT OF SENILE GANGRENE.

JONES (*Medical Chronicle*, January, 1898) lays down the following rules for the treatment of senile gangrene: (1) When the gangrene is limited to one or two toes and the patient's condition is satisfactory, the surgeon should be content with the expectant plan of treatment, taking precautions to lessen or prevent the effects of local septic infection. (2) When, however, the gangrene has reached the metatarsus, he should be prepared to perform the high operation—that is, amputation above the knee, or, in rare and favorable cases, through the knee-joint itself. The local treatment in limited forms of gangrene should consist in thorough cleansing of the foot and leg, free dusting of the immediate vicinity of the dead part with iodoform, and the application over this powder of sublimate or salicylic wool. The use of artificial heat in the form of poultices and fomentations must be discarded as not only ineffectual, but positively mischievous. Pain may be relieved by the internal administration of opium and the local application of a powder composed of boric acid, sublimate of bismuth, and hydrochlorate of morphine. A case is reported of amputation through the lower third of the thigh for gangrene of the leg in a man aged fifty-seven, who a fortnight after the operation was pronounced to be out of danger and making a very good recovery. —*British Medical Journal*, March 12, 1898.

#### THE SURGICAL TREATMENT OF CONGENITAL ANO-RECTAL IMPERFORATION CONSIDERED IN THE LIGHT OF MODERN OPERATIVE PROCEDURES.

MATAS (*American Journal of Obstetrics and Diseases of Women and Children*, December, 1897) contributes an article under this title, in which he reviews the various procedures that have been suggested with the view of overcoming intestinal obstruction caused by congenital ano-rectal imperforation. They may be grouped as follows:

##### A. Lower or infrapelvic operations.

##### I. Involving the soft parts only.

1. Puncture or incision, with dilatation of thin membranous septa or diaphragms which separate the anal cul-de-sac from the distended enteron above.

2. Typical perineal proctoplasty, with or without excision of the anal cul-de-sac, when this exists.

##### II. Perineal methods involving the pelvic skeleton, in order of severity.

1. Coccygeal displacement backward.

2. Median sacro-coccygotomy.

4. Parasacral incision.

5. Single osteoplastic sacro-coccygeal flap.

6. Median sacro-coccygotomy with bilateral osteoplastic flaps.

##### III. In all of these procedures the peritoneum may be purposely and freely opened for exploratory purposes.

##### B. Upper or primary abdominal methods.

1. Primary median or lateral exploratory celiotomy, to recognize anatomical position of rectal ampulla and detach it from the peritoneum or mesentery, so as to create a perineal anus, without colostomy.

2. Secondary median or lateral exploratory celiotomy, with same object, after failure of previous perineal exploration.

3. Secondary inguinal colostomy, after failure of perineal exploration, with immediate attempt to restore continuity of rectal outlet to anus, after drainage of bowel, the rectal end being guided to the perineum by a probe introduced through colostomy orifice.

4. Primary colostomy without perineal exploration, with secondary attempt at restoration of continuity of bowel to perineal anus at another sitting.

5. Inguinal colostomy with permanent artificial anus in left iliac region, or cecotomy when the sigmoid flexure and colon are missing.

6. Enterotomy, when condition of patient is too critical to risk further exploration for rectum or colon; this can be applied successfully in sacral as well as in inguinal regions.

The conclusions that can be drawn from the detailed study of these methods the author states as follows:

1. The most prevalent varieties of congenital ano-rectal anomalies, especially the types of imperforation which most urgently call for surgical relief, are amenable to successful treatment by the perineal route. The cases that would justify primary colostomy are in the minority.

2. There is no external sign or physical criterion by which we may determine the

actual anatomical conditions before operation in the majority of cases. The presence or absence of the anus, the coexistence of pelvic (osseous) deformities, the evidence of fistulous communications with the ano-genital tract, are all suggestive but unreliable indications of the anatomical situation and relations of the rectal ampulla.

3. Neither can we depend upon the introduction of guides into the bladder or vagina to determine the presence or absence of the enteron or to indicate its relative position in the hollow of the sacrum. The use of the exploring aspirating needle is also fallacious and is often positively dangerous, owing to the risk of peritoneal contamination.

4. The direct causes of death in imperforate infants are: stercoræmia, peritonitis, exhaustion, which rapidly set in from intestinal obstruction and stercoral stasis, and favor the absorption of toxins and the migration of intestinal micro-organisms. The influence of these causes in determining the results of operations is directly proportional to the length of time that has elapsed since birth; *ergo*, the earlier the operation is undertaken the better will be the result.

5. The resistance of the imperforate infant to traumatism is inversely proportional to the time that has elapsed since birth. The longer operative interference is delayed the less will be the resistance to shock. The experiences related in this paper emphasize this well established proposition and demonstrate that the new-born infant, when free from sepsis, compares most favorably with the adult in the capacity to resist traumatism. The experiences obtained in recent operations with sacrectomy and with the combined sacro-abdominal operations emphatically confirm the dicta of Bodenhammer (1860) and Girdalès (1865), who were foremost among the masters of the past generation to repudiate the tradition that the new-born infant is incapable of resisting severe traumatism.

6. The ideal result of operative interference in these cases is the restoration of the intestinal outlet in its normal situation or in the perineo-sacral region, with perfect functional (sphincteric) control.

7. The only way in which this result can be accomplished without subsequent evil effects is by proctoplasty performed in accordance with Amussat's rules.

8. In order to insure the best functional results (sphincteric) the operator should endeavor to avoid unnecessary injury to the sphincter and levator fibers by making strictly

median incisions. When these muscles are absent or unavoidably injured, Gersuny's axial rotation of the bowel will probably prove the most effective preventive of incontinence.

9. The older methods of relief by puncture or incision, without proctoplasty, are no longer justifiable except in purely membranous obstructions, though even the vast majority of these require excision followed by proctoplasty.

Whenever there are dense strictures or diaphragms at the junction of the anus and rectum, it is indicated to resect the stricture or diaphragmatic portion and to suture the normal rectal mucosa to the anal margin.

10. The intraperitoneal exploration of the pelvis through a perineo-sacral opening, as suggested by Stromeyer and since practised deliberately by a number of operators, is not only a legitimate procedure, but it is one of the marked advances in the treatment of this class of cases.

11. Intraperitoneal exploration through the perineum should be systematically resorted to whenever a reasonable exploration of the subperitoneal tissues fails to reveal the rectal pouch.

12. The suggestions made to amplify the primary perineal incision by the removal of the coccyx (Amussat - Verneuil), excision of the sacrum (Kraske and his followers), by osteoplastic sacral flaps (Heinecke, Roux, *et al.*), and by parasacral incisions (Vincent, Zuckerkandi, etc.), are adjuncts of value both in facilitating the search for the enteron and in perfecting a proctoplasty without dangerous tension in the lower pelvic outlet.

13. It is preferable as the method of election, in every case in which a perineal incision is insufficient to reach the enteron, to adopt the coccygeo-sacral route by a free medial incision through the cartilaginous coccyx and sacrum, as practised by Vincent and advocated by Sieur and others. If more space is required a bilateral osteoplastic flap can be easily made, which will afford a larger entrance into the pelvis without permanently sacrificing the osseous framework.

14. The predisposition to rectal prolapse after sacrectomy should not be forgotten, and for this reason as little of the bone should be sacrificed as possible.

15. Primary exploratory laparotomies, with the view of identifying the anatomical relations of the enteron and guiding the bowel to the perineum from above, are not indicated as a rule; and thus far, at least in the few

cases in which it has been tried, has not been followed by encouraging results, mainly, no doubt, because of the distended condition of the bowels and the crowding of the upper pelvic strait upon the distended sigmoid and the rectal cul-de-sac, which compels enterotomy and a consequent greater risk of peritonitis before the rectum can be guided to the perineal level.

16. Since the advent of the perineo-sacral route, with or without intrapelvic exploration, the great majority of ano-rectal imperforations, irrespective of their anatomical peculiarities, are amenable to successful treatment by the formation of an artificial anus in the perineo-sacral region.

17. The perineal anus can be formed by attaching the terminal portion of the colon (rudimentary rectum) to the perineal or perineo-sacral wound, which is the ideal result; but in emergencies it is justifiable to attach the small bowel to the perineo-sacral wound.

18. The mortality of colotomy, in the statistics thus far recorded (whether primary or secondary), is greater than that of perineal or even sacral proctoplasty.

19. (a) Inguinal colotomy as a primary procedure is indicated only when the infant is seen in an exhausted condition at a late hour, days after its birth, when stercoræmia, peritonitis and exhaustion are present, and life is ebbing fast. Then some sacrifice of ultimate benefits must be made for the sake of time. (b) In every other condition the perineal incision should initiate the primary effort at relief.

20. Median or lateral exploratory laparotomy is indicated when, after the intraperitoneal exploration through a perineo-sacral incision, it is evident that the terminal cul-de-sac of the rectum or any portion of the colon cannot be brought down to the pelvic outlet and only the small intestine is available for proctoplasty. Under such circumstances, if the condition of the patient is good, it is justifiable to perform exploratory laparotomy to identify the lowest portion of the bowel, if only to avoid the possibility of a physiological error. The aim of the operator should then be to guide the colon, the cæcum, or the most available loop of ileum to the perineo-sacral wound, where it can be drained permanently with greater safety.

21. If for any reason the operator should prefer to make an iliac colostomy (Littre), he should always consider the possibility of restoring the anal outlet of the rectum by a

secondary operation on the lines suggested by Chassaignac, Lannelongue, and others.

22. The perineo-sacral anus, if properly performed, is almost certain to be voluntarily controlled in the course of time; the iliac anus is far more uncertain in this respect.

---

*ABORTION WITH SEPTICEMIA; TREATMENT BY ANTISTREPTOCOCCIC SERUM; RECOVERY.*

CAMPBELL (*British Medical Journal*, Jan. 29, 1898) records a case of puerperal septicæmia successfully treated by antistreptococcic serum. The highest temperature reached was 104° F.; pulse 135. One injection of ten cubic centimeters of the serum was practised. The temperature almost immediately fell and the symptoms subsided by lysis.

---

*THE FIRST COMPLETE REMOVAL OF THE HUMAN STOMACH IN AMERICA; PROBABLY ALSO THE FIRST TOTAL GASTRECTOMY IN THE WORLD.*

HEMMETER (*Medical Record*, March 19, 1898) reports the first complete removal of the human stomach in America; probably, also, the first total gastrectomy in the world. He notes that Schlatter in reporting his unique cases of complete removal of the stomach asserts that the recorded cases of gastric excision are instances of partial, chiefly pyloric, removal of the stomach. Schlatter narrates the case of Langenbuch in which seven-eighths of the stomach was removed. Recovery followed. This, as well as Schuchardt's case in which only a narrow strip of the stomach near the cardia was left, can from the functional standpoint be regarded as a total excision. Schuchardt's patient lived two and a half years and apparently enjoyed perfect health. Ewald referred to the abolition of the human stomach in which about an inch of the cardiac end had been excised. The patient died three days afterward from hemorrhage. Perhaps the advance in surgical technique of Schlatter's successful case is that he has shown a successful way of union between the esophagus and jejunum. The value of this new operation consists of and is limited to the advance represented by this simplification. The second advantage which medical science might gain from the operation—i.e., the contributions to the knowledge of digestion in general and of metabolism—is realized by studies and operations made previous to esophageal enterostomy.

The main object of Hemmeter's contribution is to call attention to the fact that the first total ablation or extirpation of the human stomach was executed in America long before Dr. Schlatter's operation, or long before that of Dr. Bernays in this country. It was performed by Dr. Connor, of Cincinnati, and is reported in the *Centralblatt für Chirurgie* for 1885. This surgeon attempted to unite the esophagus with the duodenum without attempting the esophago-enterostomy which was later on successfully carried out by Schlatter. The patient lived thirty-six hours. Schlatter's operation was performed September 6, 1897. The duration of life after esophago-enterostomy should on the average be as favorable as after pyloric resection, because the latter is an equally serious operation. Schlatter does not state how long his operation required, but he remarks that his esophageal and duodenal clamps when removed had remained in position for over two hours. The consensus of experience points unmistakably to the conclusion that in malignant disease of the stomach gastro-enterostomy gives the best results obtainable whenever there are secondary metastases or adhesions. It is not necessary to give predigested foods, as the intestine is capable of digesting a certain amount of food to maintain the nitrogen equilibrium. A case like Schlatter's will probably not occur once in a thousand presented for operation, and the patient has not lived long enough to disprove the presence of minute metastases, impossible to discover even after laparotomy.

---

CONSERVATION OF THE OVARY AFTER  
HYSTERECTOMY AND HYSTERO-  
MYOMECTOMY.

HOWARD KELLY (*British Medical Journal*, Jan. 29, 1898) states that Sir Spencer Wells struck the first blow in favor of conservatism when he reported the first one thousand cases of ovariectomy in which the ovariectomy was unilateral—that is, one ovary was left—in 228 women who survived the operation and were under forty years of age; 120 of the 228 women bore 230 children, very nearly an average of two children to each woman. Of the women who were over forty years of age there were four who bore children. There is a growing conviction that the ovary belongs to the same group of organs as the thyroid, thymus, and pineal glands, and that in addition to its function of ovulation it secretes a substance which is absorbed and consumed in

the animal economy, and which is necessary to it in retaining its physiological balance.

The ill effects of castration, whether the organs are diseased or not, are often disastrous. Two natural lines of experiment have been tried. It has been shown that the ovaries may be completely severed from their normal surroundings and successfully transplanted either to a part of the broad ligament or the muscles of the abdominal wall. The second line of experimental substitution of the lost ovarian tissue is that of feeding to the women deprived of ovaries one of the organic juices. The results reported by Chrobak were extremely encouraging.

Stehman also reports having procured great amelioration of the symptoms incident to the induced climacteric by the administration of thyroid tablets. A consideration of physiological facts should lead the gynecologist to practise the utmost conservatism in treating the essential organs of sex. Since the spring of 1895 Kelly has invariably made an effort to retain the ovaries, even in those cases in which it has been necessary to remove the uterine tubes and the uterus; the result of this has been a remarkable diminution, and in some cases complete absence, of the distressing nervous symptoms of the menopause.

He reports twenty cases in which the uterus was removed for myomatous or fibroid tumors. In general no hospital cases have been included in a list of later date than December, 1896, although eighteen have been operated on since that time. In every case, of course, the uterus was removed; in eleven instances one ovary and in six instances both, and in ten both uterine tubes. Three of the cases could not be traced. Of the remainder the operation in not a single instance gave rise to any of the aggravating symptoms so commonly associated with the artificially induced menopause. The utmost discomforts experienced were slight flushes; and in nine cases absolutely no symptoms of a menopause are noted. One patient in her thirties, after experiencing no symptoms of the menopause after cessation of the menstruation, began two years after the operation, and fully from four to six years earlier than natural, to pass through the various nervous phenomena of a menopause of ordinary character.

The operation is easy if the tubes are left and the operation is begun by tying off the broad ligament at the uterine cornu, including the isthmus of the tube and the utero-ovarian ligament in the first tie, tying the broad ligament next, and then exposing

the base of the broad ligament, ligating the uterine vessels, amputating the uterus at the vaginal junction, clamping the uterine vessels of the opposite side, and then pulling the uterus up and out, and ligating the round ligament, the tube, and the ovary at the opposite cornu.

Kelly has not gone to the length of attempting to retain inflamed or diseased tubes and ovaries, which can be much more quickly and safely removed in conjunction with the uterus.

#### *A CASE OF PERFORATING GASTRIC ULCER; LAPAROTOMY; RECOVERY.*

In line with several articles on operation for perforating gastric ulcer, the following interesting case is detailed. The patient was under the care of Dr. S. F. TOOGOOD (*The Lancet*, Jan. 15, 1898).

It is probable that the most important factor influencing the result of a laparotomy for a perforated gastric ulcer is the length of time which has elapsed since the perforation. In no recorded case has recovery ensued if the operation has been postponed for more than twenty-four hours, unless extensive peritoneal adhesions existed prior to the perforation. In the following case the operation took place about fourteen hours after the rupture. The sooner the operation is performed the better, though it has been considered advisable by some to wait until the reaction has replaced the first shock of the perforation.

A servant aged twenty-one years was admitted into the Lewisham Infirmary about 1.30 A.M. on September 17, 1897, with the history that she had been suffering from gastric ulcer for some months past and had been attended by Mr. Leonard Stokes. On the 16th, soon after noon, she was seized with sudden acute pain in the region of the stomach, and she fainted. Mr. Stokes promptly diagnosed the rupture of the ulcer, and as soon as the necessary arrangements were completed she was conveyed to the infirmary. On admission she was suffering severely from collapse; her pulse was 130 and very feeble, and the respirations were 34, almost entirely thoracic, and shallow. She complained of intense pain over the whole abdomen, the wall of which was rather distended and was kept very rigid. Percussion revealed that the liver dulness had disappeared in front. Chloroform was administered and Dr. Toogood opened the abdominal cavity by an incision three inches long be-

tween the xiphoid cartilage and the umbilicus; there was a considerable amount of free gas in the cavity. The stomach was seen lying quite collapsed and was found attached by a ring of adhesions to the anterior abdominal wall; a portion of these adhesions had broken down, and the forefinger could easily be passed into the stomach. This attachment necessitated the original incision being continued for about three inches along the left costal margin, when the site of the ulcer was thoroughly exposed. The adhesions were divided with care, but no vessels required ligature. The ulcer appeared as a punched-out hole of the size of a sixpence.

The condition of the patient was so alarming that it was decided not to pare away the thickened edges of the ulcer; accordingly the gap was drawn together by twelve Lembert sutures, using 00 Chinese twist silk and a very fine milliner's needle. Nearly a pint of dark fluid mingled with debris of food was sponged out of the abdomen, and several gallons of sterilized water at a temperature of 110° F. were used in washing out the peritoneum. Special attention was paid to the liver and the interstices between it and the diaphragm, which as well as Douglas' pouch were well sponged out, and a thick strand of cyanide gauze was passed on each side well down to the posterior edge of the liver. The incision was now closed by silk-worm-gut sutures except at the upper angle, where the gauze drains were protruding. The wound was dressed on the same day at 6 P.M., when the gauze drains were removed; that from the right side, being almost dry, was not reinserted, but that on the left was replaced by a Keith's glass tube, having a cyanide gauze wick in its center. During the next forty-eight hours the wound was dressed four times, a good deal of cloudy serum collecting in the tube; but this having ceased, the tube was removed sixty hours after the operation.

Immediately after the operation the temperature sank to 99.4°, but eighteen hours afterward it had risen to 103.6°. However, it again sank, and after a few unimportant fluctuations it gradually became normal and remained so after the fifth day. The pulse improved with the temperature. Three minims of morphine injected hypodermically with one-fiftieth of a grain of strychnine were given every twelve hours for three days. A teaspoonful of hot water was allowed by the mouth every two hours.

Dr. Toogood has found that with a long

tube and with great care and slowness a nutrient enema measuring a full pint may be successfully given, and this amount of peptonized milk with peptone of beef was administered every six hours, while the bowel was thoroughly washed out once in the twenty-four hours with a simple enema.

Seven days after the operation fluid food was commenced by the mouth, one ounce of peptonized milk flavored with Benger's or Mellin's food being given every four hours. After a lapse of two days this amount was given every two hours, and this was gradually increased until in three weeks' time five ounces every two hours was being taken. Twenty-five days after admission the nutrient enemata were discontinued and arrowroot was given by the mouth; after the thirty-first day three ounces of pounded chicken was taken daily; and after the lapse of another week the patient was able to take an ordinary light diet.

The wound healed by first intention with the exception of the track caused by the tube, which granulated slowly, but it was soundly closed in three weeks. About the tenth day a good deal of abdominal pain was complained of which caused much perplexity, until a too sympathetic fellow patient was detected administering bread and butter. The pain ceased with the sympathizer's removal. The patient was discharged plump, ruddy and well on November 20.

#### TUBAL PREGNANCY.

CHASE in the *Brooklyn Medical Journal* for February, 1898, contributes an article on this subject and advocates the following treatment:

If the surgeon or accoucheur should be so fortunate as to detect a case of tubal pregnancy before primary rupture, no time should be lost in relieving the woman of danger involved in rupture. But one of two methods can be pursued after rupture—either reliance on the *vis medicatrix natura*, or the surgical art. Removal by excising the tube by laparotomy is the plain and unmistakable indication, and nothing short of this adequately meets the gravity of the situation. The hemorrhage must be controlled.

Should the ovum chance to die before primary rupture, the contents, together with effused blood, may absorb, or suppuration with its consequences may follow, in which event knowledge of the fact might not be disclosed until the operation. If the case is seen

at or immediately subsequent to time of primary rupture, the same rule holds good. By reasoning that the hemorrhage may cease spontaneously and thus deferring operative interference, the golden opportunity of saving a life may be lost. If some time has elapsed since the rupture, then the necessity for interference may not be imperative, and opportunity may be had to watch the development of the case to determine whether the mass enlarges, diminishes, or remains stationary—and from such data the rule of action will be formulated, according as the life of the ovum is or is not retained.

Surgical experience generally, and here in particular, confirms the truth that the risk of operation is far less hazardous than the continuation of the hemorrhage, which may not cease until life is extinct.

In operation for primary tubal rupture the abdomen should be opened from above, the bleeding arrested by ligation of open blood-vessels, the placenta, ovum and clots removed. Operation *per vaginam* offers inadequate space to effectively control bleeding vessels, and at the same time to be certain of having removed everything requiring removal. If the rupture is in the distal portion of the tube, its removal will include the sac and contents, unless new attachments have formed between it and some portion of the pelvic cavity immediately contiguous. If it is intraligamentous the new formation may be so perfectly removed and the control of the hemorrhage so complete as to warrant the closing of the broad ligament opening by running catgut suture. If not, one of two methods is admissible—either stitch the walls of the sac to abdominal opening, packing the same with gauze enclosed within a Mikulicz bag, or better still, make an opening from the broad ligament cavity into the vagina, either laterally or through Douglas' cul-de-sac, according to its location. Pack the sac with gauze, first carrying the end into the vagina, and closing the abdominal wound. The advantages of downward drainage, when possible, are too obvious to require comment. If for any reason pelvic drainage is needful—as might happen from infection—it should be downward by gauze into the vagina. For this reason the vagina should always be made sterile before commencing the operation.

If recent, the clots are best removed by free irrigation with normal salt solution. If, however, the clots have been within the pelvic cavity for several days, and are attached to the pelvic viscera, only gentle measures

should be used for the detachment, for the risk of tearing the intestines more than counterbalances any disadvantages from their presence. The peritoneum in most cases will take care of blood-clots not infected.

If death of the embryo follows rupture, and effused blood remains either in the pelvic cavity or imprisoned with the broad ligament, the subsequent behavior of these cases is like that of pelvic hematoma. Under such conditions, particularly in the extra-pelvic variety, vaginal incision may be, and often is, the better method of approach. Then the blood and débris may be removed, and efficient drainage established without risk of infecting the peritoneal cavity.

Every facility for thorough and rapid work should be at hand in these operations, and for this reason, other things being equal, the best results are likely to attend the work in a well equipped hospital. The necessity, oftentimes, of placing the patient during the operation in the Trendelenburg posture is imperative and without it failure would ensue. It is highly essential for the patient's safety, in presence of exhausting hemorrhage and shock, that sparteine, strychnine, digitalin, or nitroglycerin be administered hypodermically according to the existing indications. So, too, high rectal enemas of hot normal salt solution may be advantageously employed with a view of augmenting the fluid in the circulation. If this is unavailing, intracellular or intravenous administrations of normal salt solution are the remedies *par excellence*.

---

REMARKS ON THE SURGERY OF THE VAS DEFERENS RELATIVE TO SOME URINARY DISORDERS.

The following interesting and instructive statements are made by REGINALD HARRISON (*The Lancet*, Jan. 8, 1898):

Judging from various communications that have recently appeared both in British and foreign journals, an increased experience tends to confirm the favorable view taken of division or resection of the vas deferens in certain urinary disorders in the author's Bradshaw Lecture. He proposes supplementing these remarks on this important subject:

In speaking of partial resection of the vasa deferentia relative to the enlarged prostate, it must not be supposed that either it or any other proceeding will meet all forms and degrees of this affection, or that its results will be uniform. A moment's consideration at once renders this intelligible. There is a

tendency as age advances and when the meridian is passed towards a fibrotic degeneration of the testes and prostate, in which the latter gradually ceases to be glandular and becomes transformed more or less into masses of unstriped muscular fiber and connective tissue. When this condition is far advanced the part is only amenable to that kind of treatment which applies equally to other fibrous growths wherever they are situated within the body. Castration and vasectomy may both alike fail under these circumstances, and some form either of prostatectomy or prostatotomy, should the necessity arise, is more likely to be successful and permanent. Similarly in carcinoma of the prostate we have a condition where no good results are to be expected, though it must be said that in one or two instances, where division of the vasa was practised and the growth eventually turned out to be a cancer, it does not appear that any harm was done. Excluding, however, such exceptional cases as these, which we are now learning to discriminate, and allowing for the degree of fibrotic degeneration that the parts undergo, there can be no doubt that in vasectomy we have a valuable and fairly certain means of removing the distress that a hypertrophied prostate in the usual acceptation of the term occasions. The weight of evidence in reference to this, the author thinks, is now sufficiently conclusive and may be safely acted upon. Further, it tends to show that if vasectomy fails castration is not likely to do otherwise, though the selection of the former does not necessarily preclude a subsequent trial of the latter.

There can be no doubt that castration is a serious undertaking in the case of many persons of advanced years enfeebled by illness as compared with vasectomy, and the risk connected with it is not inconsiderable. On the other hand, if vasectomy is performed under certain conditions it is not open to these objections. As prominent among the latter the author would again urge that though a resection of a part of the seminal ducts is a minor proceeding, it is better not to operate upon both canals simultaneously, but on two separate occasions with a short interval between. That physiological effects of an active kind not limited to the urinary organs sometimes follow upon the simultaneous removal of the testes, and less rarely on the simultaneous resection of the vasa, there can from recorded cases be no doubt. In some they have taken the form of cerebral

disturbance and in others of mental decay, which have marred the good effects of any structural changes in the prostate which have also followed. The author has neither seen nor heard of such results as these being observed where both vasa were not divided at the same time. Excision of these ducts is, however, a slower mode of effecting prostatic shrinkage than castration, as it entails the induction of a double process of atrophy—that is to say, by means of an atrophy following upon a preceding one. In this lies, he believes, in a great measure its safety. Whilst improvement usually commences at once on the completion of the operation and steadily advances, it is sometimes several weeks and even months before the full amount of benefit is reached. In a recorded case of suprapubic fistula following an operation where double vasectomy was performed for the purpose of causing a diminution in the size of the prostate and the restoration of the natural passage for the urine, over four months elapsed before the fistulous opening quite closed and urination was again normal. The patient was sixty-six years of age and made a complete recovery, though no further treatment was employed. Other instances have come under notice where the maximum amount of good was not reached for even longer periods than this.

In the following instance progress, was slow, but it would have been impossible to have brought about so much comfort with a prospect of more by any other means. In November, 1895, the author saw a man, aged seventy years, who, in addition to glycosuria, was suffering from a large prostate with much obstruction and residual urine. In spite of treatment with the catheter and other means his symptoms increased. Early last year (1897) the frequent calls to attempt micturition and the great pain and difficulty in using the catheter and the general distress induced the author to advise vasectomy. The first vas was divided on April 13 and the second on May 11; from these dates he steadily but slowly improved. In a letter to the author (December) he writes: "I certainly am very much better than I was, and so long as I am quiet and able to carry out my regular treatment I get on very comfortably." He uses his catheter five or six times in the twenty-four hours, and can now void some urine voluntarily. The author has good reason for believing that he will still further improve. As the fibrotic condition of the parts was much advanced at the time of

operation, it would have been better if it had been performed earlier.

And this brings the author to remark that, having regard to the time often occupied by the prostate before it assumes a form or a size calculated to seriously obstruct micturition so as to necessitate operative interference, the sudden and active induction of its atrophy may be open to objection for reasons which may possibly be explanatory of what he has referred to as more frequently following upon simultaneous removal of both testes. We are only, as it were, beginning to study in view of their application for therapeutical purposes the physiological effects of certain changes produced by the addition to, or withdrawal from, the body of certain organized parts or materials. In the case of the former we have some evidence of this in effects produced by the introduction of toxins and animal alkaloids, while the latter may be demonstrated as following removal of the thyroid gland. On all grounds, therefore, the author prefers to bring about the changes desired in the prostate in the way he has always advocated. The cases in which benefit has followed vasectomy have been those where the symptoms were induced directly or indirectly by senile enlargement of the prostate gland. Amongst these we may include very frequent and painful micturition, difficulty with and frequent use of the catheter with much spasm and hemorrhage, and the more severe forms of cystitis arising from obstructed micturition. In some of these instances the division of a single tube has proved efficient. Further, in certain recurring cases of stone depending on sacculation or pouching of the bladder complicating prostatic hypertrophy, the induction of atrophy of the latter has afforded some excellent results. The probable explanation is due in all these examples to what the enlarged gland undergoes, and consequently to the greater freedom with which urine is passed or the catheter is introduced. In all cases where vasectomy is practised, before both tubes are divided it is well to ascertain that the bladder is quite free from stone. He has met with more than one instance where a small calculus was passed after a vasectomy which had previously been undetected by a sound. Probably it had been concealed or pouched by the large prostate, and had escaped spontaneously as the latter decreased in size.

Further, the enlarged prostate is often a serious detriment to the kidneys by establishing a back pressure of the urine, which can

be most injurious to these organs. He refers to that class of cases where the urine excreted under pressure is constantly of a low specific gravity. Here, as Sir James Paget observed, "there will be danger from the most gentle catheterism." The author has seen low densities in urine rise steadily to normal and remain so, after the tension has been taken off micturition by the induction of atrophy of the prostate. It is not unlikely that we may find in vasectomy another means for removing intrarenal tension. It must be remembered that it sometimes takes but very little to render a prostate obstructive. Sir Henry Thompson pointed this out in connection with his important studies on the pathology of this gland. The author has seen enough to convince him that a small amount of shrinkage, provided it takes place in or indirectly affects the right spot, makes all the difference as to whether a man leads a life of comfort or not.

It is not unlikely that this operation will be extended to other disorders of the urinary organs. Though the normal function of these ducts is that of conveying the seminal fluid from the testes to the vesicles and prostatic urethra, they are equally capable of transmitting micro-organisms in both upward and downward directions. In this sense they may therefore be regarded as distributors of disease. Some years ago, soon after he had published a short article on division of the vas deferens relative to prostatic hypertrophy, he saw a delicate young man with a strong tuberculous family history with a nodule in his left testicle remaining after an acute gonorrhea. This nodule was deemed to be tuberculous or likely to become so. The question then raised had reference more especially to the removal of this by operation on the ground of its suspicious nature. The urine was healthy, and so was the opposite testicle and its tubes. Nor was he able to discover any evidence of deposit, so far as the finger could reach, either in the vas or the prostate. The patient, who had had some medical education, was anxious that either the nodule or the testis should be removed. The author did not feel disposed to recommend either course. Having regard to the fact that the disease appeared limited to the nodule and that any infection would probably pass along the canal of the vas deferens, he proposed to excise a portion of the latter. This was done, and the wound healed in a few days. A year afterwards it was found that the testis and nodule had both com-

pletely atrophied, and no signs of tuberculous infection could be detected. The patient's health and sexual powers remained unimpaired.

The second group of cases of transference of infection through these ducts may be illustrated by the inflammations that take place of the testes and tubes occurring in connection with some cases of prostatic hypertrophy where catheterism is necessary and often difficult. This is a complication which, when frequently repeated, seriously adds to the gravity and pain of these disorders. Early in the year 1896 the author saw a man approaching seventy years of age, otherwise in good health, who, in addition to much prostatitis, repeatedly suffered from most painful epididymitis in one or both organs, though sexual power had ceased for some years. He was dependent on the catheter. These attacks had been going on for some months, almost entirely confining him to bed and preventing him attending to his business. The author divided his vasa for him with great relief so far as his prostatic symptoms generally were concerned, and since this was done he has had no further trouble with his testicles.

The author has tried various methods for resecting the vasa. The simplest appears to consist in rendering the vas superficial by manipulation of the scrotum and making a small incision over it. It can then be easily seized with a Spencer Wells' clamp forceps and brought to the surface, where it is practically isolated by a little scraping and a blunt hook or aneurism needle passed beneath it. A loop is included by a silk ligature and the free portion removed by scissors. To ligature the duct is insufficient, it being necessary to resect a portion of it. After the loop has been removed the stump is returned with the ligature cut short, and the little wound is then closed with a suture or collodion. Union usually takes place in the course of a day or two. In this way the operation can be performed quickly, and almost bloodlessly.

In concluding these remarks the author need hardly suggest that patients should invariably be made to understand, whatever their ages may be, that though division of one duct does not interfere with the function of generation, the subsequent section of the second duct entirely and permanently extinguishes any sexual power that the individual may have previously possessed. The operation may therefore be said to be restricted to that

period of life and to coexisting circumstances when the general function relative to the urinary disability is ceasing or has ceased to be a matter for consideration. The cases must be extremely rare where in earlier years the damage occasioned by the hopeless loss of all control over this function calls for such measures as vasectomy would undoubtedly supply. Further, he would repeat in connection with the latter operation, as well as with other procedures of a like nature, that they are only applicable to grave varieties of prostatic disease and other complications arising out of them. When we recognize how many elderly men carry on long and useful lives who are more or less dependent upon the aid their catheter affords, it is hardly necessary to say that such measures can only apply to exceptions and not to the rules. The latter are already adequately provided for, whilst in the interests of the former all proved methods either of cure or of relief must receive our careful and unbiased consideration.

*LEFT SUBCLAVIO-AXILLARY TRAUMATIC ANEURISM; LIGATION OF SUBCLAVIAN ARTERY IN ITS SECOND PART; RECOVERY, WITH PERFECT USE OF ARM.*

CROLY (*Medical Press and Circular*, Feb. 16, 1898) reports a successful case of ligation of the subclavian artery in its second part. The patient was wounded by a stab in 1893. In 1895 he exhibited a large, pulsating tumor occupying the subclavicular and axillary space. The upper extremity was wasted. In December, 1895, operation was performed. A vertical incision was made along the outer border of the sterno-mastoid muscle, and a horizontal incision was carried parallel to the clavicle and almost its complete length. The entire origin of the sterno-mastoid was divided; the tumor was found occupying the third portion of the subclavian artery. The outer border of the anterior scalene, which had been turned backward by the pressure of the tumor, was raised and divided by a pair of blunt scissors. The operator scraped through the deep fascia and exposed about a quarter of an inch of the subclavian. The sheath was incised, and an especially long, deeply curved aneurism needle with a large eye was passed about the artery from below and within, upwards and slightly outwards. This needle was armed with a ligature made of ox-peritoneum and was tied on the side next to the heart by the first hitch of the

reef-knot. The operator merely approximated the internal coats, as suggested by Scarpa, and used no violence whatever. The second ligature was applied in the same manner, and finally the four ends were drawn as a single ligature, holding two in each hand, and tied in the second hitch of the reef-knot. The advantage incident to using two ligatures is that a greater extent of the intima of opposite sides is brought into contact. The wound was washed out with warm carbolic lotion, and the edges closed with gut sutures. The wound closed without complication and the patient recovered completely. Croly quotes from literature a number of other interesting cases.

*INFLATED RUBBER CYLINDERS FOR CIRCULAR SUTURE OF THE INTESTINE.*

HALSTED (*Bulletin of the Johns Hopkins Hospital*, February, 1898) states that it is bad surgery to employ stitches which enter the lumen of the intestine. It is impossible to suture the serosa alone. It is impossible to suture unfailingly the serosa and muscularis alone, unless one is familiar with the resistance offered to the needle by the submucous coat of the intestine; furthermore, stitches which include nothing but the serous and muscular coats tear out easily and are not to be trusted.

Each stitch should include a bit of the submucosa. A fine thread of this coat is much stronger than a considerable shred of the entire thickness of the serosa and muscularis. It is not difficult to familiarize one's self with the resistance offered to the needle by the submucosa, and with a very little practise one learns to include a bit of this coat in each stitch.

The mattress stitches are to be preferred to Lembert's, because one row of them is sufficient, because they tear out less easily, oppose larger surfaces and more evenly, and constrict the tissues less than Lembert stitches do.

In circular suture of the intestine, only one row of stitches should be taken, and the entire row should be applied before a single stitch is tied; otherwise it is impossible to preserve a straight line in the taking of the stitches, and the stitches taken last may be much farther from the cut edge than those taken first, and the flange turned in may be so broad as to occlude the intestine's lumen.

Before the intestine is resected, its blood-

supply should be most carefully studied, with reference not only to the placing of ligatures, but also of the stitches, and the stitches should be so placed that the circulation, up to the very edge of the parts to be sewed, shall be as perfect as possible.

The results obtained by adhering strictly to the foregoing rules have been so perfect that the author has employed no other method in his practise.

Halsted holds that license to practise general surgery should be withheld from those who have not practised on animals the operations for circular suture of the intestine and intestinal anastomosis. As a case in point he recalls an instance in which a surgeon asked his assistance in performing a circular suture of the intestine. He readily consented to practise the operation upon dogs. At first his dogs all died. He finally succeeded in saving more than fifty per cent. of the dogs operated upon. The operation on his patient required five hours, but was successful.

Experts in intestinal surgery, almost without exception, prefer to perform circular suture of the intestine without the use of mechanical devices.

Halsted holds that his own operation, previously described, is by no means satisfactory, notwithstanding the very perfect results which attended its employment in the hands of others as well as himself. The disadvantages of his original method and of all similar methods were as follows:

They required about twenty minutes to perform the operation.

One or two assistants at the wound were indispensable.

Clamps or the fingers of an additional assistant were necessary to prevent the escape of intestinal contents.

The vermicular action of the intestine (particularly in dogs) was a great annoyance, for it prevented an accurate disposition of the stitches. Stitches applied as near together as possible during the intestinal contraction might be too far apart in the stage of relaxation.

If the pieces of intestine to be united were not of the same size their adjustment might be very difficult.

The rolling out of the cut edges of the intestine prevented in places recognition of the precise edges, and hence the operator might not know how far from the edge he was placing his stitches nor just how much intestine he was turning in.

The handling of the intestine by assistants

who act as clamps or who hold parts in place during the stitching must be injurious to the tissues and predispose to infection.

Every one of these objections is disposed of by the employment of the rubber cylinders.

The diameter of rubber cylinders and their application are illustrated by a series of admirable drawings; the first of these shows the application of the presection stitches. It is immaterial whether these stitches perforate the wall of the intestine or not, for they are eventually cast off into the bowel. The intestine should be carefully divided with scissors as close to the presection stitches as possible. No visible blood-vessels are occluded by these stitches.

For the human small intestine the diameter of the cylinder is from  $1\frac{1}{4}$  to  $1\frac{1}{2}$  inches. The fourth figure shows two of the presection stitches tied, and the collapsed rubber cylinder is being pushed into the bowel with a forceps. The next figure shows three presection stitches tied. They are supplemented by a fourth stitch, which is removed later to facilitate the withdrawal of the bag. The bag has been inflated with air by the syringe. Then follow figures showing the insertion of the mattress or permanent stitches. The first of these and the most important perforates the mesentery twice and picks up the submucosa four times. It insures the proper turning in of the mesenteric border. From ten to twelve mattress sutures suffice in operations upon the human subject; the first stitch to be tied down is that which secures the mesenteric border. The advantages of the inflated rubber cylinder in circular suture of the intestine are as follows:

The vermicular action of the bowel is arrested over the bag, and the stitches can, consequently, be placed at regular and proper intervals.

The distended bag unrolls and spreads out to a fine edge the everted raw edge of the intestine and enables the operator to place the stitches with great precision at the desired distance from this edge.

If distended intestine is to be sutured to collapsed intestine (in strangulated hernia, ileus, etc.), or intestine of larger to intestine of smaller lumen (jejunum to ileum, duodenum to esophageal end of the stomach, etc.), the smaller may easily be expanded to fit the larger piece.

Very little handling of the intestine itself by the operator is necessary. The tube from bag to syringe is used as a handle to rotate and elevate the parts to be united.

The cylinder takes the place of at least two assistants. The operation could readily be performed without an assistant.

The entire operation, exclusive of suture of the abdominal wall, can be performed on dogs in five or six minutes and probably in less time.

#### PLASTIC OPERATION FOR SADDLE-NOSE.

WARBASSE in the *Brooklyn Medical Journal* for February, 1898, contributes a paper with this title in which he states that the introduction of foreign bodies for prothetic purposes into the tissues, and the securing of the healing-in of the same, still remains a surgical procedure of unfixed utility. That this can be accomplished has long since been demonstrated. The material best adapted to be used for this purpose and the permanency of such operations are the questions yet to be settled.

An operation which the author performed for the relief of saddle-nose is as follows: An incision is begun at the muco-cutaneous junction about half-way down the ala of the nose, and carried upward along the margin of the nostril, across the septum, and down on the opposite side to a corresponding point. This incision is made just within the nostril. The skin is then dissected up over the whole extent of the external nose. This dissection is carried on with a narrow knife and sharp-pointed scissors. The skin is thus dissected free from the alæ and the cartilaginous tip of the nose, and laterally out upon the superior maxillary bone and its nasal process to the canthi of the eyes, and above as far as the frontal bone. The chief bleeding comes from the vessels of the septum and the branches of the angular artery. This is controlled by twisting the bleeding points, by the application of pressure, and by packing the wound with hot compresses. This procedure, over so great an extent and through so narrow an opening, must needs be very tedious. Complete hemostasis having been secured, a bridge of hard rubber is inserted, and the wound closed by a subcuticular suture of silk. Over the whole is then placed a dry compress, which is held in place by adhesive straps, and which is intended to make gentle pressure and act as a splint.

The patient upon whom the author operated was a man forty-two years of age, who suffered since childhood with an aggravated deformity of the nose, a sequel of scarlet fever. All that remained of the nose was the cartilaginous tip, which had also been re-

tracted by the sinking in of the bridge of the nose, so that the nostrils looked upward more than normal. The bridge was made of hard rubber, concavo-convex in form. The two wings of this bridge were widely fenestrated, and when in place rested upon the nasal process and facial surface of the superior maxillary bone.

At the end of forty-eight hours all dressings were removed, and the suture line painted with collodion. The traumatic edema had almost disappeared by the end of ten days, and at the end of two weeks it had quite subsided. There was never any discharge from the wound. The subcuticular sutures were drawn out at the end of ten days. It is now twelve months since the operation, and the patient has suffered no irritation whatever from the presence of this bridge beneath the skin. The nose presents a normal appearance.

#### MODIFICATION OF SCHEDE'S THORACOPLASTY IN CASES OF EMPYEMA.

SUDECK (*Deutsche Zeitschrift für Chirurgie*, 47 Bd., 2 and 3 Heft, 1898) proposes what he considers a serviceable modification of Schede's operation of thoracoplasty. Schede's operation he describes as follows: An incision is to be made beginning at the outer border of the pectoralis major at the level of the fourth rib, curved downward to the lower margin of the pleural cavity, then upward, outward and backward to the middle of the scapula, which is thrust out of the way by turning the arm upward over the breast. This flap is raised and the whole chest wall, including the second rib, is resected. The remaining cavity is filled in as far as possible by a musculo-cutaneous flap. The greatest difficulty is experienced in so arranging this that the apex of the pleural space is carried in. There often results a persistent fistula.

This operation is usually performed on extremely weak tuberculous individuals. It is therefore important that the operation should be as simple as possible, and it would seem advisable to complete it at several sittings.

Sudeck's method is as follows: The first incision begins at the cartilaginous insertion of the fourth rib and runs horizontally outward and backward across the scapula as far as the vertebral arch. Parallel with this incision a second is made on a level with the floor of the suppurating cavity. These two

incisions are connected in the axillary line by a vertical cut making the figure H. The two flaps on the bar of the H are then turned forward and backward. The ribs are resected from the tenth to the third inclusive, and the thoracic walls, together with the thickened pleura, are removed throughout the whole extent of the cavity as far as the second rib. In spite of the shrinkage which occurs in the flaps, when they are spread out it will be found possible to nearly cover the remaining exposed pleural surface, the tongue-like flaps being stretched past each other. They are held in place by packing, and the part which is uncovered remains an open surface. At the second sitting this can be covered either by transplantation or skin grafting. At the third operation the depression made by the costal pleural at the apex of the lung can be closed either by transplanting the flaps or by resection of the second rib.

#### TEMPORARY GASTROSTOMY FOR CICC- TRICIAL STRICTURE OF ESOPHAGUS.

VILLARD, in reporting a case of the above character, expresses the opinion that we must not consider gastrostomy as a definitive procedure, but rather as a temporary measure, to give the operator time to adapt his means to his case, and to give rest to the esophagus, thereby suppressing the spasmodic and inflammatory condition of that organ, and allowing the surgeon to resume the necessarily suspended catheterization. The following observation confirms these views: A woman aged forty-five years had a cicatricial stricture for the past four years, due to ingestion of sulphuric acid. Regularly catheterized, this woman was fed through the esophagus until June, 1897, when, from unskilful catheterization, deglutition even of liquids became impossible. This woman, after ten days of absolute diet, was in a very bad general condition, weighing only 39 kilogrammes (about 75 pounds). Villard then performed gastrostomy in two sittings, and for nine days the patient was fed through the stomach. Esophageal catheterization then became again impossible, as well as deglutition of liquids. From this on regular dilatation of the esophagus was performed.

Two months later an operation was done to obliterate gastric fistula; autoplasty with three planes of suture; an insignificant fistulette, persisting for some time; complete cure

in November; the patient had then gained eleven kilogrammes. At present she is fed by the mouth regularly and catheterized from time to time, so as to maintain the caliber of the esophagus. This is not, however, a unique case. In a report by Lefort, comprising sixteen patients, thirteen recovered with a permeable esophagus after gastrostomy; and in one case of Jabouley, of Lyons, gastrostomy performed almost *in extremis* enabled esophageal catheterization twenty days after, with a complete subsequent cure. — *Journal of American Medical Association*, Jan. 22, 1898.

#### THE MANAGEMENT OF PATIENTS BEFORE AND AFTER LAPAROTOMY.

WIGGIN (*Medical Record*, Jan. 22, 1898) concludes his paper on this subject as follows, calling attention to the points which he considers important, though usually classed as minor ones:

1. The importance, whenever practicable, of prolonged preparatory treatment of patients about to undergo an abdominal operation.
2. The importance of the administration of cathartics in the early part of this period, followed by large enemata for the purpose of cleansing the intestinal tract.
3. The importance of keeping a record of the body temperature, respirations and pulse-rate for several days in advance of the operation, and of making a final examination of the urine.
4. The necessity in the female of arranging to have the operation performed a few days after the menstrual period, and the cleansing of the vagina, even when it is intended that the operation shall be by the abdominal route only.
5. The administration of a small quantity of peptonized food (one ounce) containing stimulants two hours before giving the anesthetic, for the purpose of lessening the tendency to nausea and vomiting after the recovery of consciousness.
6. The necessity of the anesthetic being given by an experienced physician, and in the smallest possible quantity.
7. The necessity of protecting the patient's body properly with clothing and blankets during the operation.
8. The advantage of stimulating the pulse before the heart has become much exhausted, and of using intravenous saline injections before the radial pulse has become extinct.

9. The leaving in the abdominal cavity after free irrigation of a quantity of hot saline solution, for the purpose of stimulating the patient, preventing (?) the formation of intestinal adhesions, and lessening the danger of septic infection of the peritoneum.

10. The necessity of making the patient comfortable by change of position during the first two days of convalescence, and by the use of the rectal tube.

11. The necessity for the early administration of food in reasonable quantities and at proper intervals.

12. The necessity of withholding stimulating enemata after operations in which extensive and firm pelvic adhesions have been broken up.

13. The necessity for deliberation as to the wisdom of reopening the peritoneal cavity in a given case of supposed concealed hemorrhage.

14. The importance of washing out the stomach as soon as the diagnosis of intestinal paresis is made, and of the persistent use of saline cathartics till the bowels move.

15. The importance of not administering cathartics to those convalescing from abdominal operations, and who are pursuing a normal course, too early or in too large doses.

#### OPERATIVE TREATMENT OF CANCER OF THE RECTUM.

Dr. DESFORGES-MEREIL (*Journal des Praticiens*) describes an operative procedure which he considers eminently fitting for this affection. After having successfully passed in review the coccygeal, sacral, parasacral, vaginal, perineal, and abdomino-sacral ways, the author concludes that it is best to return to the perineal method of Lisfranc, modified by himself as well as by other modern surgeons. This method is the most convenient and the surest, as it permits the entire lesion to be laid open, and allows us to see its connections with other neighboring organs. From a clinical standpoint the author establishes, according to the anatomical divisions of the rectum, two classes of rectal cancers—the recto-pelvic cancer, extending from the third sacral vertebra (superior limit of the rectum) to the levator ani, and the recto-perineal cancer, extending from the levator to the anal orifice. Every cancer situated above the third sacral vertebra the author considers as a tumor of the sigmoid flexure and not a cancer of the rectum. The true

cancer of the rectum should be treated by the sacral method or by prerectal extirpation and suture of the two ends by a special method of the author's, which he calls recto-pelvic. The recto-perineal cancer would justify the amputation of the rectum according to Lisfranc's method, and suture of the rectum in the levator ani (the process of the writer). In inoperable cases an iliac anus will be found expedient, made by special process of the author. Those processes of extirpation have been tried on the cadaver and on the dog, and have given the author excellent functional results.—*Medical Record*, Jan. 22, 1898.

#### CHRONIC GONORRHEA AND ITS SCIENTIFIC TREATMENT.

VALENTINE (*Clinical Record*, January, 1898) summarizes his paper read before the Pan-American Congress and calls attention to the fact that Oberlaender strongly advocates dilatation of the urethra, holding as among its advantages easily obtainable practical asep-sis; painless introduction of instruments and the precision of dilating only those spots which the urethroscope shows to be diseased; cessation of the morning drop; no temporary or permanent disadvantages to the patient or his occupation.

None of the dilators, excepting Kollmann's irrigating dilator, should be used without soft rubber covers. These covers should fit snugly and should be tested by turning the screw to its full capacity before the instrument is inserted. The straight dilator is used in the treatment of disease of the anterior urethra. Dilatation should be accomplished slowly and very gently. Shortly before removing it a solution of potassium permanganate, 1:6000, should be prepared with which to make an irrigation either of the urethra or the bladder, as occasion may require. In cases of pronounced urethral hyperesthesia cocaine or eucaine should be used before instrumentation. Dilatation as a rule should be practised about once a week. The amount of dilatation should be governed by circumstances. As a general rule it is safe to dilate two numbers in the beginning; after twenty-eight is reached, one-half, or one number. At the first dilatation the instrument is left in position from three to five minutes. From this time it may be increased by two or three minutes at each session. The extent to which dilatation may be made depends upon the caliber of each individual urethra. When

the patient is cured, then the maximum dilatation required is reached. The patient should always be put in the recumbent position, and extreme gentleness should rule in the use of the instruments. Erections following the use of dilatations may be prevented by the use of monobromate of camphor. When potassium permanganate does not improve a urethritis, corrosive sublimate (1:50,000 to 1:5000) or silver (1:5000 to 1:1000) may be successfully employed. When the prostate and seminal vesicles are involved, or the posterior urethra, they should be subject to massage at least twice a week before each irrigation. The third day after dilatation irrigation is advisable. Should early dilatation be followed by great increase of the discharge, the following dilatation should not exceed the number reached at the previous seance. This repetition of the same number should occur until the following discharge is trifling; then the increase may be one, two, or even three numbers at each sitting. The only correct guide in treatment is urethroscopy. The exact region to be dilated can be determined only by the urethroscope.

The danger which this treatment offers lies in the anxiety of the physician and patient to hurry the case, both observing the almost immediate improvement—to hurry the case by increasing the rapidity of the dilatation and reducing the intervals between each session.

Relapses during treatment are not rare. They are commonly due to sudden and violent dilatation or to new infection. Cases occasionally present in which the urethroscope, after persistent dilatations and irrigations, reveals no infiltration, no abnormality of the folds or striation, no cicatricial bands, to explain the persistence of discharge, especially the morning drop and filaments in the urine. Injections, painting the urethra with caustics, etc., prove of no avail. Then careful search of the urethra will discover, perhaps, only a few gaping orifices of gland ducts. These when treated through the urethroscope put an end to the manifestations of disease.

Kollmann has devised a fine syringe which can carry silver nitrate solutions into the glands, his sharp curette can scrape, and, these failing, they can be destroyed by his electrolytic needles, designed for the purpose.

When old gray-looking cicatricial masses do not yield to dilatations, Oberlaender recommends splitting them with his endoscopic knife. Successive punctures of the

infiltrates with Kollmann's electrolytic needle, followed each time by irrigation, have proven successful. When filaments persist even after urethritis is cured, they probably come from the prostate or seminal vesicles.

Chronic posterior gonorrhea often yields temporarily to mild injections of silver nitrate. Relapses are frequent. Dilatation followed by irrigation often yields prompt and satisfactory results. The treatment of masturbator's urethritis does not differ from that described. One of the most useful drugs is monobromate of camphor in sufficiently large dose to quiet sexual irritability.

Valentine advises the positive prohibition of the so-called diluents—*i.e.*, effervescing mineral waters. The patient may, however, take large quantities of water or milk and water, but certainly not carbonaceous beverages. When it is positively proven that patients suffering from chronic urethritis harbor no gonococci, and when no active, acute, inflammatory condition remains, moderate sexual intercourse need not be specifically prohibited.

## Reviews.

---

A SYSTEM OF PRACTICAL MEDICINE. By American Authors. Edited by Alfred Lee Loomis, M.D., Late Professor of Pathology and Practical Medicine in the New York University, and William Gilman Thompson, M.D., Professor of Medicine in the New York University. Volume III: Diseases of the Alimentary Canal, Peritoneum, Liver and Gall-Bladder, Spleen, Pancreas and Thyroid Gland, Chronic Metal Poisoning, Alcoholism, Morphism, Infectious Diseases Common to Man and Animals, Miscellaneous Subjects.

Philadelphia and New York: Lea Brothers & Co., 1898.

The volume of this system at present before us opens with Diseases of the Alimentary Canal. To Richard C. Cabot is assigned the task of describing the affections of the mouth and adjacent structures as well as of the salivary glands. This is accomplished in a manner eminently satisfactory in a general work, and the article is of value for the terse manner in which is described a series of diseases of common occurrence. The consideration of Diseases of the Oesophagus is undertaken by Allen A. Jones, and that of Diseases of the Stomach by Charles G. Stockton and Allen A. Jones conjointly. The latter writer in discussing organic stricture of the esophagus is made by the text to say "The stricture may be *angular* in form," etc. We presume this to be a typographical error, annular being the word intended, as the text

continues, "new connective tissue proliferation being evenly distributed throughout the whole circumference of the tube." The section on Diseases of the Stomach is preceded by a chapter upon the general examination of the stomach and the examination of the gastric contents, which adds much to the value of the section. We are glad to notice that the writers at this point, and when discussing Carcinoma of the Stomach, give due importance to the presence and detection of lactic acid in the gastric contents. It is properly pointed out that the late investigations of Boas show the unreliability of Uffelmann's test as employed after the exhibition of Ewald's trial-meal. It is a matter of regret, however, that the writers should have been so indefinite in their statements that the student upon learning this fact must search elsewhere for the knowledge to apply Boas' test. In the treatment of Chronic Gastritis the writers give a timely hint against the too frequent administration of lavage, a method of treatment of great value, but undoubtedly in many instances improperly employed. This entire section is one of the most valuable in the volume.

Diseases of the Intestines are well described by William W. Johnston and Henry M. Lyman. W. F. McNutt contributes a thorough and painstaking article upon appendicitis. He decries the tendency of the present day to eliminate the term "typhlitis" from medical literature, and deplores the fact that so little regard should be given to the possibility of the occurrence of inflammation of the cæcum as well as of the appendix. The article throughout is vigorous in tone, and the endeavor is made to place the disease again firmly among those that are "medical," in contradistinction to those that have purely a surgical significance. The position assumed by the writer may best be indicated by quoting from his text: "Always operate when serious doubt arises as to the necessity for an operation. That skilled and experienced surgeons are justified in operating earlier and oftener than unskilled and inexperienced operators goes without saying. While surgeons call appendicitis a surgical disease, under some of the circumstances already mentioned the surgical treatment should be strictly confined to opening an abscess when fluctuation can be distinctly made out; and inexperienced practitioners are fully justified in using carefully the exploratory needle to diagnose the presence of pus."

It is impracticable within the limits of this

review to specifically mention all the noteworthy articles contained within this volume. An article of much interest, however, is that upon Food-Poisoning, by Victor C. Vaughan, a subject, though of daily increasing importance, usually given scant attention in works of this character. The article calls for no comment, as the author's name sufficiently places it.

H. A. Hare, in a well considered article, describes the Diseases of the Peritoneum. It is evident that in the acute inflammations of this structure the writer demonstrates a tendency to yield to the spirit of the age which is taking the affection from under the control of the physician and transferring it to that of the surgeon. He says—and very properly we hold—"We believe that in all cases of peritonitis the outlook for the patient will be better if at the first a surgeon be called in to study the case with the physician." The author prefers to treat the affection by opium in large doses rather than by the use of saline purgatives. Indeed, he points out so many accidents likely to happen under the administration of purgatives that the impression is conveyed that their use at all is deprecated. Nevertheless, the writer hints at one very serious objection to the treatment by opium when giving as a reason for the advisability of an early surgical opinion "that the surgeon may grasp all the details of the case before any of them are set aside by opium." It is thus tacitly admitted that an obscuration of the symptoms indicating the necessity for operative interference attends the use of opium.

Diseases of the Liver and Gall-Bladder are most ably presented by J. E. Graham. This is the largest individual contribution to the volume, and the subjects are given thorough and scientific consideration.

Other noteworthy articles are those upon Diseases of the Spleen, by George Roe Lockwood; Diseases of the Pancreas, by Charles G. Stockton; Diseases of the Thyroid Gland, by Francis P. Kinnicutt; Chronic Metal-Poisoning, by Frederick G. Finley; Alcoholism and Morphinism, by James Stewart. The Infectious Diseases Common to Man and Animals are also ably considered by James Law.

It is evident that between the writing and the publication of some of the contributions to this volume a considerable interval of time has elapsed, as the most recent advances in several instances have failed of notice. This is a fault of all Systems, however, and one

which, on the whole, the one now under review possesses in a minimum degree.

The present volume, like its predecessors, is an example of what is best of the publisher's art.

T. G. A.

THE NERVOUS SYSTEM AND ITS DISEASES. A Practical Treatise on Neurology for the Use of Physicians and Students. By Charles K. Mills, M.D. Copiously Illustrated.

Philadelphia: The J. B. Lippincott Company, 1898.

Dr. Mills has presented us with a volume of nearly eleven hundred pages upon this very interesting field of study in medical science. He points out in his preface that the great work of Gowers is the only extensive treatise on Nervous Diseases in the English language, and that he has thought that the compilation of the present volume will present to the profession a full consideration of the many recent additions to the anatomy and pathology of the nervous system. The volume is dedicated to Dr. Weir Mitchell, which, of course, is an exceedingly appropriate act, considering the relations of Dr. Mitchell to neurology and to the medical profession of Philadelphia. An examination of the pages of the book reveals one thing which we think is to be regretted, namely, that enough care has not been given to the illustrations, which, while they generally show what they were intended to show, are not executed as well as their importance deserves.

In the chapter on the General Therapeutics of Nervous Diseases we fail to see why Dr. Mills has made differentiation between "alterative tonics" and "metallic tonics," for all of the alterative tonics that he mentions are metallic tonics. The facts which are cited in the short page devoted to Bromides are certainly not as inclusive of the facts which we know concerning these preparations as one would expect to find in so exhaustive a manual, and we do not think that enough emphasis is laid upon the limitations of these preparations or on the fact that they are capable of doing harm.

We are glad to see Dr. Mills has the courage of his convictions and does not hesitate to mention the particular products which he has found valuable in his personal practise. Notwithstanding these facts, however, we think that this portion of the book in a future edition ought to be considerably modified, for if there is one thing above another which medical literature needs to-day it is some book which will embody most of the valuable points in the therapeutics of nervous diseases, for at the present time these diseases

are more interesting to the physiologist and pathologist than to the general practitioner, owing to the limited treatment which can be accorded to them. This is partly due to the characteristics of the diseases and partly to the faulty and imperfect study of their therapy.

It is in the chapters which study the microscopic and macroscopic anatomy of the nervous system that Dr. Mills' book first strikes us as being exhaustive and useful, and it is to this part of scientific neurology that Dr. Mills has devoted many years of constant labor. Those who attended the First Congress of American Physicians and Surgeons in Washington will remember the brilliant summary of neurological knowledge which he presented in his address to the Congress on that occasion, and it goes without saying that since that time his study and contributions to medical literature have been such as to render these chapters in his book exceedingly useful.

One point which strikes us as being of value in the work is the fact that almost every page reveals Dr. Mills' personal clinical experience, and that the illustrations are, so far as the patients are concerned, many of them original. It was the "original" characteristic of Gowers' book, coupled with the fact that he was able to present neurological facts in an interesting manner, that made that work successful, and Dr. Mills' accuracy in the study of diseases, his love of his theme, and his ability to teach, have produced a volume which bids fair to rival its older antagonist.

DOCTOR AND PATIENT: HINTS TO BOTH. By Robert Gersuny. Translated by A. S. Levetus. With a preface by D. J. Leech.

Bristol, England: John Wright & Company, 1898.

Opposite the title-page of this book, the object of which is well expressed in its title, are quoted the words of Professor Nothnagel, "Only a good man can be a good doctor;" and in its brief seventy-nine pages this is the text upon which the author continually writes.

The first chapter deals with the Relative Position of Patient and Doctor, with Confidence in the Choice of the Doctor; the second with the First Visit, the Examination of the Patient and His Complaints; the third, with Common Sense and Cheerfulness. Then follow others on Diagnosis and Prognosis for the Patient and His Friends; the Action of the Physician in Desperate Cases; on the Frequency and Length of the Doctor's Visits; on the Misconstruction and Abuse of the

Doctor's Statements and Gossip. Other chapters are provided upon the Harmful Influence of the Persons about the Patients; upon Household Remedies and Quack Doctors; of Corruption of Doctors by the Public; Consultations and Fees.

We are sorry that this useful little book, which will prove invaluable to old as well as young physicians, has not been published by an American publisher, but as any one of the large booksellers can readily obtain it, and as its cost is but fifty cents in a good binding, we trust that many of our readers will take enough interest in it to carefully peruse its pages. It is written in a light and useful vein well qualified to amuse as well as to instruct, and the ground covered by its chapters we have already indicated.

As Professor Leech well says in his preface: "We cannot rise from the perusal of this book without feeling better for the wise counsel it gives and without having received an incentive to do that which is right and maintain at its highest point the honorable position of the profession."

A COMPENDIUM OF INSANITY. By John B. Chapin, M.D., LL.D.  
Philadelphia: W. B. Saunders, 1898.

Dr. Chapin has devoted so many years of his life to the study and cure of the insane, and has had such an unusual experience in one of the largest insane asylums in this country, namely, the Pennsylvania Hospital for the Insane, and other institutions, that anything which he may write upon his specialty will necessarily attract the interest of medical men in general and of alienists in particular. The book which he has presented to us is a small octavo volume of 227 pages, and this indicates that the text is not particularly diffuse or exhaustive, for the type is large and the leading heavy. The chapters of the book deal with Idiocy and Imbecility, Insanity and the Definition of the Terms, Insanity, the Actions of the Insane, the Classification and Nomenclature, and a chapter upon three of the forms of melancholia. This is followed with one upon the Treatment and Management of Melancholia, while Chapter IX deals with the various forms of mania and its variations. Then follow chapters upon the treatment of Mania, Dementia, Paresis, Epilepsy, and Abnormal Psychical States; the two final chapters of the book being devoted to Morbid Anatomy, Medical Certificates and Feigned Insanity.

As the chapter on Morbid Anatomy only covers seventeen pages, it will be seen that in

this portion of the book at least the text is by no means exhaustive. Indeed, we consider that this chapter is one of the weakest in the volume. The illustrations are good and the text is written in a brief manner, rather in the form of a talk with the reader upon the subject of insanity than with the design of preparing an exhaustive monograph.

As an illustration of the views of an alienist of wide experience the book is of value. Dr. Chapin has been known far and wide throughout the profession for his high ideals as a professional alienist, and we doubt, therefore, whether he will approve of the announcement of the publisher that "Owing to its clear, untechnical language it will prove a useful manual to the legal profession and will afford information of the utmost value and interest to the layman, enabling him to recognize insane tendencies and to provide intelligently for any case of insanity in the family that he may be called upon to care for temporarily." A little knowledge is a dangerous thing, and the records of the medical and legal professions are strewn with the wrecks of families where one member has been insane enough to believe that the others needed his parental guidance and the care of an asylum, when as a matter of fact it was he that was insane. We cannot imagine any department of medicine in which a faulty knowledge of disease upon the part of the layman can produce so much unhappiness for himself and his friends as in that branch of medicine which deals with nervous diseases and the study of the insane.

AN ATLAS ON THE ESSENTIALS OF PATHOLOGICAL ANATOMY. By Dr. O. Bollinger. Volume IX: Diseases of the Circulatory, Respiratory and Digestive Apparatus. Illustrated with Colored Plates.  
New York: William Wood & Company, 1898.

This volume is like the rest of this series which we have already reviewed, consisting of an Atlas of Ophthalmology by Haab, of Nervous Diseases by Jakob, and of Gynecology by Schaffer, with the exception that Pathological Anatomy is so large a subject that it will fill two volumes, of which this is the first. The book is also identical in its scope and apparently belongs to the same series as the Atlas of Clinical Medicine by Jakob, issued by another publisher, which we review in this number of the GAZETTE. Its price is also \$3.

This volume is by far the best of any of the series. The colored plates are unusually well chosen, singularly well executed, and illustrate in a peculiarly lifelike (or to speak

more correctly, a peculiarly deathlike) appearance the pathological changes which have taken place in the various organs of the body. It is evident from the imprint on the plates that they are all imported, and the lithography of Germany and Austria is celebrated the world over for its faithful portrayal of anatomical material. There are few books which are sufficiently good to arouse the reviewer's enthusiasm. This is one of them.

**A LABORATORY TEXT-BOOK OF PATHOLOGY FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE.** By Horace Whitacre, B.S., M.D. Illustrated. Philadelphia: P. Blakiston, Son & Co., 1898.

This book, which is just received for review, has the aim, we are told in the preface, to state in clear terms the principal facts which are needed by the student in working with his microscope in the laboratory. It covers a little over 150 large octavo pages, and almost every page has one or two illustrations taken from micro-photographs, dealing with the tissues which are described in the text. The author is anxious that it should not be considered by the reviewer as an exhaustive treatise on Pathology. He only claims that it is a summary which will be of value to the student in his laboratory work. Some of the illustrations are very good, but that on page 161 representing the pigmented plasmodium malarie in the stage of segmentation is very poor, and that on page 162 is not any better. The text itself, as far as it goes, is clear and to the point. Those who are interested in the teaching of pathology may find that this volume is of use to them, while others who have different methods of teaching will probably find that it does not agree with the course of teaching which they have designed.

**AN ATLAS OF METHODS OF CLINICAL INVESTIGATION.** With an Epitome of Clinical Diagnosis and of Special Pathology and Treatment of Internal Diseases. By Christfried Jakob. Edited by A. A. Eshner, M.D. Profusely Illustrated with Colored Plates. Philadelphia: W. B. Saunders, 1898.

This is an exceedingly useful little manual to the practising physician. The treatise showing areas of various organs in health and disease as they are outlined by the methods of clinical diagnosis are colored and unusually good. There are also very good plates showing the most important color reactions of the gastric juice, and a large number of colored plates showing the condition of the blood in various diseases, of the microscopic particles which are found in the secretions of the mouth, and other cavities of the

body, and finally there is a section of some 200 small octavo pages devoted to the consideration of clinical diagnosis.

Because of the plates the price of the book is necessarily above that usually charged for a volume of this size, namely, \$3.

**ANNUAL AND ANALYTICAL CYCLOPEDIA OF PRACTICAL MEDICINE.** By Charles E. Sajous, M.D., and One Hundred Associate Editors. Assisted by Corresponding Editors, Collaborators, and Correspondents. Illustrated by Chromo-lithographs, Engravings, and Maps. Volume I. Philadelphia: The F. A. Davis Company, 1898.

The lack of punctuation on the title-page of this the first volume of the successor of the Annual of the Universal Medical Sciences, a publication which is familiar to most of the profession in this country and abroad, suggests the startling idea that a similar lack of commas and other punctuation marks, if found through the text, would cause the reader some difficulty. An examination of the text, however, shows that it has been more carefully edited and as a rule very well written. The present volume is bound in linen and is pleasing in appearance. It covers 600 pages, the text being printed in double columns, which are a little narrower than those of the THERAPEUTIC GAZETTE. Four styles of type are used—large, black-face type for headings, smaller black-face type for sub-headings, good-sized print for the ordinary text, and a smaller type for references and for text which is not considered particularly valuable.

Therapeutics has been laid aside as a separate department, and the articles on various diseases are followed by articles upon their treatment. Illustrations, as in the old Annual, are exceedingly creditable so far as the chromo-lithographs are concerned, but many of those without colors seriously lack printers' ink. At the beginning of the volume a statement is made of the editorial staff, which consists very largely of those whose names are already familiar to the readers of the Annual, since their functions have simply been transferred from one publication to another.

The present volume extends from Abdominal Injuries to Bright's Disease, which will give some idea of its scope and that of future volumes. To those who have become fond of the arrangement of the Annual as previously published this book will doubtless appear somewhat strange, but through it all the skill of Dr. Sajous as an editor is manifested, and we doubt not that on the appearance of the complete set of volumes

the profession will be even more pleased with the product of his labor than they have been with the monument which he has already erected to himself in medical literature.

### LONDON LETTER.

BY RAYMOND CRAWFORD, M.A. OXON., M.D., M.R.C.P.  
LOND.

We regret to have to record the death of Sir Richard Quain at his residence in Harley Street on March 13. Though in his eighty-second year he devoted himself to the duties of his profession up to the last few months of his life. Indeed, he transacted from his death-bed much of the business of the General Medical Council, of which he had been an indefatigable President since the year 1891, when he was elected to the presidency on the death of Mr. John Marshall. The attractions of his personality assured to Quain the professional success which he had enjoyed ever since the early years of his career. Yet we should hardly deem him one of those physicians of whom this country should be most rightly proud. Quain was great, not because of any contributions to medical science of first-rate importance, but like Johnson, because of his Dictionary. The editorship of this colossal work was undertaken by him at the busiest period of his professional life, and the thoroughness of the work and the success it has attained are evidence of the fact he spared himself no pains in its compilation. His own principal contributions to the Dictionary were the articles on Angina Pectoris, Diseases of the Bronchial Glands, and Fatty Degeneration of the Heart—the latter subject being one with which his name will always be associated in medical literature. It is estimated that over 50,000 copies of the Dictionary are in the hands of the profession. Quain was never elected President of the College of Physicians, in spite of his untiring energy in its service, and is said to have been keenly disappointed at not securing what he deemed "the blue ribbon of the profession."

The death of Sir Richard Quain vacates the presidency of the General Medical Council. There is a generally felt wish that Sir William Turner, who has already done the duties as deputy, may consent to undertake the office. This, however, would probably necessitate his residence in London, and retirement from the Chair of Anatomy in Edin-

burgh; and it remains to be seen whether Sir William Turner will feel himself bound to make these personal sacrifices for the benefit of the profession.

On March 16 the President of the Local Government Board introduced the Vaccination Acts Amendment Bill into the House of Commons. Clause I fixes the age limit within which the child shall be vaccinated at twelve months instead of three months as heretofore, and the parents are not compelled to take the child to the public vaccinator. We certainly approve the longer limit of age, as many children at three months are quite unfit for vaccination; the necessity also of obtaining a certificate of unfitness has certainly disposed some parents unkindly to vaccination. It is also desirable from the side of vaccination, as we shall have much less syphilis attributable to the vaccinator that should rightly have been traced to the parents. Clause II provides that the public vaccinator of the district shall, if the parents wish it, visit the home of the child for the purpose of vaccinating it. This provision of domiciliary vaccination is in response to the recommendation of the Vaccination Committee. With the general use of calf-lymph the necessity for arm-to-arm vaccination is done away with, and the vaccination "center" is to be a thing of the past. Under Clause III, if a child is not vaccinated within nine months after its birth the public vaccinator of the district shall visit the home of the child, and offer vaccination with glycerinated calf-lymph. This seems to us by far the most important innovation of the Bill. In the first place there can be no question of transmission of syphilis by calf-lymph; and further, the multiple secondary infections of the infant with erysipelas, tubercle and other micro-organisms cannot be laid to its charge. The large supply of calf-lymph that will be required will necessitate considerable enlargement of the establishments at which it is prepared, but this has been satisfactorily adjusted by arrangement with the Institute of Preventive Medicine. A further clause abolishes repeated penalties for non-compliance with the Act. Repeated penalties have not been found successful in coercing parents, and have at the same time stirred up much unnecessary antagonism to vaccination. Mr. Chaplin has very properly declined to accept the recommendation of the Commission that any parent who had a conscientious objection to the practise should be excused on making a statutory declaration

to that effect. Such a concession would have made any legislation on the matter of vaccination nugatory. Indeed, it is a matter for apprehension lest the removal of repeated penalties should deprive legislation of much of its compulsory power. The Bill should certainly have gone a step further in securing the welfare of the community by providing for revaccination on the same lines as for initial vaccination. Knowing as we do the limited duration of immunity it is certainly a serious omission that no provision should have been made for encouraging adult vaccination.

Recently records have appeared in several of the medical journals of cases of Addison's disease that have been treated by suprarenal extract. In this country the disease is so comparatively rare that it hardly falls to the lot of any physician to see sufficient cases on which to base a generalization, and one must needs trust the evidence of accumulated records. Two years since Ringer and Phear collected all the cases recorded in medical literature. Speaking generally these fell into two classes, those that derived no benefit from the treatment, and those in which there was temporary improvement of muscular strength, now and again associated with some diminution of intensity of the pigmentation. M. Bécclère, a French physician, has recently recorded a case in which improvement only set in five months after commencement of treatment, and was then maintained for three years and still showed no sign of abatement. It seems as though the suprarenal extract exercises some beneficial influence on the healthy residue of suprarenal capsule, possibly inducing hypertrophy; at any rate, it can hardly be that the extract supplies some substance which the disease of the capsules has removed from the economy. Our own experience extends only to three cases: Of these, two were very advanced cases of the disease at the time at which treatment was commenced, and there was no improvement of any kind even in the degree of muscular vigor, and each case ended fatally. The third case is somewhat more promising in that the disease is in an earlier stage, but at present after three weeks of steady treatment there is no apparent amelioration.

I have recently seen in King's College Hospital what must be an almost unique therapeutic triumph. In the first place an hour-glass contraction of the stomach was correctly diagnosed by Dr. Burney Yeo, and in the second place it was operated upon by

Mr. Watson Cheyne with what appears likely to be permanent relief. The history of a gastric ulcer seventeen years ago was quite definite, and the subsequent symptoms pointed very clearly to pyloric obstruction from cicatrization of the ulcer. The points which aided the diagnosis of hour-glass contraction were the excessive distention of the cardiac end of the stomach—a condition which was not present in the pyloric end of the stomach—and on auscultation over the middle of the stomach a gurgling sound could be heard from time to time as though fluid were running through a narrow orifice. The operation performed by Mr. Cheyne was the so-called Heincke-Mikulicz operation. A vertical incision was made over the stomach in the midline about four inches in length, and the stomach drawn out of the wound; it was at once seen that an hour-glass contraction in the middle of the stomach was to be dealt with. The constriction was so tight that a moderate-sized catheter could only just be passed through it. There was a great deal of cicatricial tissue about the constriction, and a complete absence of mucous membrane over its surface. The constriction was then divided transversely, and the incision extended for an inch or more into the healthy tissue on each side of the cicatrized portion. By bringing the extremities of the wound together a considerable addition of space was provided for the passage of food, as in the operation of pyloroplasty. The wound was stitched up first with a row of stitches through the whole coats of the stomach, and then with a row of Lembert's sutures. Mr. Cheyne would have preferred to excise the whole cicatrized portion and unite the divided ends of the stomach, but the condition of the patient was hardly such as to warrant the major operation. The patient from the first made an uninterrupted recovery. For the first few days after the operation rectal feeding was resorted to, but on the fifth day she was fed completely by the mouth. In the first month after the operation she was sick only once, and this was attributable to an error of diet. It is now three months since the operation, and she is steadily gaining weight and suffers very little digestive inconvenience. It will be interesting to see in the course of a year or more what degree of contraction will occur in the neighborhood of the wound.

Dr. Joseph Griffiths read a paper of some interest to the Royal Medico-Chirurgical Society on Microcephaly and its Surgical Treat-

ment. The conclusions which he deduces are as follows: (1) That congenital microcephalic idiots may be divided into two main classes: (a) those with small ill-filled but not deformed skulls; (b) those with small and deformed skulls. (2) In the former class the brain is at fault, being arrested in its development in an early period of embryonic life; in the latter there is in addition to arrested development of the brain evident disease of the cortex, distributed in patches more or less symmetrically, the deformity of the skull being determined by the shape of the brain. (3) There is a hypothetical case in which the skull is prematurely synostosed and the enclosed brain more or less normal, but hitherto no evidence has been brought forward to show that such cases actually occur. (4) Craniectomy in all but the last named (hypothetical) case can be productive of no permanent good, as the original fault is in the cerebrum (or of the whole nervous system) and not in the skull. (5) Where there are symptoms, such as general rigidity of the limbs, etc., which are in all probability due to irritation of the motor cortical centers, then operative interference (trephining or craniectomy) is likely not only to afford amelioration of the symptoms, but in some cases to lead to a substantial and even permanent improvement. (6) Hitherto the mortality from operations has been very high, but with experience it is likely that this will be materially reduced.

In the February number of the *Edinburgh Medical Journal* are some interesting observations by Dr. Campbell Clarke on the Therapeutic Value of Spleen Extract. Briefly he summarizes its therapeutics as follows: "It aids digestion and nutrition, increases the cutaneous circulation, and stimulates the glandular activity of the skin." Dr. Clarke was led to look for some benefit from spleen extract in cases of insanity by the frequency of splenic deficiency in the insane. The first group of cases he submitted to the treatment in the asylum were cases of chronic inertia, mental and physical. Some of the cases seemed to benefit materially, and two cases even appeared to have been cured, but in the larger number the results were negative. In another group of cases where the mental condition was more promising, and had in most instances broken down under some physical strain, such as prolonged lactation, the results were far more prompt and decided. The improvement was at first mainly of the physical condition, but later the mental state followed suit, so that some recov-

ered completely, while others underwent some amelioration. The observation of these two classes of cases served to show that the splenic extract had marked influence on the skin and complexion, and the third group of cases was specially chosen to test its efficacy in this direction. In two cases—one of chronic psoriasis, the other of chronic eczema—the success was rapid and remarkable. It is impossible to detail the cases that came under treatment, but any one will be well repaid by the perusal of this most interesting paper in its entirety. Dr. Clarke commenced his investigations with home-made emulsions of spleen substance in salt solution and glycerin, but subsequently this was substituted by one of the more palatable forms now in the market. These may be had either in the form of tabloids, or of emulsion, or of fluid extract. The emulsion is an ether extract of spleen, and each fluidrachm is equivalent to five grains of extract. The limit of safe dosage seems to be about one drachm three or four times a day. Of the fluid extract one drachm is equivalent to a drachm of fresh spleen, and of this three to four tablespoonfuls may be safely given each day.

---

#### PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

---

Bacteriology is being studied a good deal by the younger men at the Faculty of Medicine, and Dr. Bezançon, chief of laboratory at the Faculty of Medicine, and Griffon have spoken lately at the Society of Biology on their researches concerning the cultivation of the pneumococcus. Gelose and bouillon are well known to be very poor mediums for pneumococci, as under such conditions they develop tardily and without capsules. Dr. Mosny has proposed rabbit's serum, and Drs. Gilbert and Fournier defibrinated blood. These two mediums are excellent, but are to be used differently. If what one wants is the characteristic appearance of pneumococci, if one wishes to isolate it from other varieties of germs, the serum of rabbit is certainly very useful, but one should choose a young rabbit. The serum of other animals may be used provided they are chosen young. But in case one wishes to keep in a laboratory some pneumococci with all their virulence, the best method is to use blood. The pneumococcus does not grow as well, but can be preserved much longer. To prevent the des-

iccation of tubes in the oven, one should add as much again of ascitic or pleuritic serum. By this method Dr. Bezançon has been able to keep several cultures three to four months. To conclude, it is well to use defibrinated blood as a means of culture and serum of young rabbit as a means of diagnosis.

The serum of Marmorek continues to be examined more or less critically by various members of the medical profession in France. This serum, which is supposed to act in cases of streptococcic infection, has been employed in a number of surgical services, and at the present time is being employed at the Beaujon Hospital in the Maternity Department. Dr. Courmont has, however, insisted upon this fact, that the serum can only act in certain cases of infection, and that the result, good in some cases, may be reduced to nothing in others, according to the variety of streptococci. This serum has also been tried in some cases of erysipelas without proving that it could be counted on as an antitoxin. One can say that the value of Dr. Marmorek's serum is not as yet fully established, and the tendency as shown by what is heard in the hospitals is that further work is needed on the subject.

At the last reunion of the Society of Therapeutics Dr. Linossin cited a case of a woman thirty years old who, under the influence of a dose of twenty-five centigrammes of exalgin taken for an attack of hepatic colic, presented an eruption of bullous erythema appearing on the body as well as on the hands. There was no pruritus, but a sensation of burning in the digestive tract. No fever was observed and no albumen found on examination of her urine. This eruption lasted four days and then disappeared. The well known pharmacologist Bardet made some remarks about this case and said that too much exalgin was given in some cases, and that a dose of ten to fifteen centigrammes only should be given to women.

Dr. Landouzy, professor of therapeutics at the Faculty of Medicine, has been publishing of late in the *Presse Médicale* a series of schematic observations of various medical cases, and giving the rational treatment to be followed out. The first paragraph of each article is given to the description of the case, its symptoms, progress, and termination. The heading of this part of the article shows that therapeutics must be "clinical in their sources of information"—for instance, a case of pachydermic cachexia in a woman sixty years old without any noticeable modification of

the thyroid gland. This condition, as shown by the article, can be mistaken for that produced by asthenia resulting from cardio-renal lesions.

The second paragraph goes to show that the means used must be "pathogenic in their indications." The cause of the disease must be well specified—*i.e.*, lack of thyroid elements—and therefore this is to be overcome by the use of the very element in question.

In the third part the treatment to be used is indicated. It must be "physiological in its means," and therefore one must supply what is lacking—thyroid gland tissue—and also tone up the nervous system perverted by the lack of proper elements.

In the final part of each article, the author describes the various remedies used and indicates minutely what should be done as to hygiene or dietetics. For instance, in the case in point:

1. The former treatment should be suppressed.
2. Each day at every meal ten centigrammes of thyroid gland of sheep should be taken in a capsule.
3. Vigorous rubbing with a flannel glove moistened with lavender alcohol every morning on upper part of body.
4. An enema every morning of 300 grammes of tepid water with ten grammes of borax.
5. Every week a dose of castor oil—twelve grammes.
6. The food taken should consist of milk-soup, eggs, cutlets, sheep's brains, beef once a day, macaroni, dry vegetables (mashed), chicory, boiled lettuce, various custards, cooked fruit, light tea. This treatment is to be modified as improvement sets in.

These short and practical articles seem to be appreciated by the students, as they indicate clearly what should be done in a given case and are up to date.

In a recent number of the *Correspondenz-Blatt für Schweizer Aerzte*, Dr. Huguenin, of Zurich, has published some important information on the hemorrhage seen in tuberculous patients in the first stages. By being able to examine the condition of the lung after death in a certain number of cases he has shown that the characteristic symptoms observed in such cases are due to well-defined bacteriological and anatomical causes. The clinical aspect offered by this variety of patient is sufficiently clear and precise. A tuberculous patient, suffering from a small ulceration of the summit of the lung, has a hemorrhage that lasts about an hour, though

without being intense. The next day the same thing occurs, and there is a continuance of this phenomenon for eight or ten days. This sort of hemorrhage is much more to be feared than the ordinary variety. One can readily understand that the blood effused is aspirated into other parts of the lung, and that on account of its consuming a great number of streptococci and bacilli of Koch it is apt to produce most serious disorders.

In several such cases Dr. Huguenin has been able to observe at the autopsy that the hemorrhage was due to the ulceration of a vein and not that of an artery. On examining the expectoration of patients suffering from this form of hemorrhage, one generally finds a peculiar sort of a clot. This clot is pediculated, irregular in form, and on examination is found to be composed of a series of layers of fibrin. In the center is a cavity containing recent clots. One can therefore consider this formation as being due to a hemorrhage inside a small excavation in the lung, with deposits of successive layers of fibrin on the walls of the excavation. Later the outer layers are attacked by the streptococci, and on account of these being modified the clot is expelled and another hemorrhage takes place.

The treatment of this form of hemorrhage is rather delicate, as coughing is necessary to expel the blood, and on the other hand this is apt to prevent the formation of a clot. Coughing should therefore be diminished without being totally suppressed, and to obtain this small doses of morphine—for instance, five milligrammes thrice daily—may be administered. Mustard plasters, dry and wet cupping and temporary ligation of the limbs may also be useful. Dr. Huguenin does not believe in the use of astringents, such as acetate of lead, tannin, alum, of ice, nor of ergotin. As to the infectious condition due to the presence of streptococci, creosote or its compounds would seem to be of use.

At the Society of Therapeutics Drs. Gallois and Bonnel have advocated the use of oxygenated water in the treatment of continued vomiting in gestation or in consumption. The solution they use is the one containing ten volumes of gas, and this solution should also contain a small quantity of hydrochloric acid to give stability to the preparation. A thing to be remembered is that one should use an active solution, and the best means of recognizing this condition is to deposit a small amount on a piece of iron, when bubbles

will appear and the iron get rusty. The dose administered is one large spoonful dissolved in a liter of water, to be taken in twenty-four hours during meals. This treatment has been of great service, but it has not been clearly proved on what one can base the physiological action of this drug. Is it due to hydrochloric acid acting upon the digestive functions, or rather to a special oxidizing influence of the oxygenated water on various ptomaines, thereby rendering the latter harmless?

---

#### BERLIN LETTER.

---

BY JAMES J. WALSH, PH.D., M.D.

---

Of interest in connection with what I said in my last letter in regard to protargol and the use of the silver compounds generally in gonorrhea, is the announcement from Vienna of a new compound of silver and albumin. This will kill, in a test-tube, gonococci in dilutions of 1:4000. Its inventor claims that it will replace protargol.

In the midst of the supreme lack of confidence in drugs that one finds among medical men over here, it is a cause of no little surprise to find that certain remedies whose mode of action is at least doubtful, and which the most refined scientific classification of therapeutic remedies can only bring under the empiric rubric alteratives, enjoy a high reputation among all classes of medical men. The iodides are a type of this class, and all the clinicians are agreed that, apart from syphilis, in all chronic inflammatory processes which have not gone on to actual degeneration, the iodides are efficient in bringing about resolution and involution of the inflammatory exudate. Professor Leyden, for instance, is sure that they do good in fibrous myocarditis and in the arterial conditions which are productive of interstitial myocarditis. Professor Mendel is convinced that he has seen two very striking effects from their use in arteriosclerosis: first, within a very short time after their employment the sharp, clanging second sound of the heart was rendered distinctly softer; second, watching the state of the radial artery carefully for a time showed that after three or four months it became distinctly softer and more elastic to the feel; thus confirming to the coarser sense of touch what the delicate heart mechanism had revealed to the sense of hearing shortly after the beginning of the treatment.

Professor Heubner uses the iodides in all diphtheria cases and finds that the diphtheritic membrane is loosened easier, and thrown off sooner, when it is employed in conjunction with the serum, than when diphtheria serum is employed alone. All of the clinicians are agreed that for aneurismal pains and the sense of persistent tenderness, sometimes amounting almost to dull pains, that occur in connection with aneurism, the iodides are almost a specific. Potassium iodide is not much employed here, the potassium being considered too depressant, so that the combination with sodium is preferred. To children where the iodides seem indicated, the saccharated iodide of iron is given. The iodides are never given in large doses; twenty grains three times a day is considered a good-sized dose for an adult, and more than this is seldom prescribed.

Two good illustrations of the protean forms that drug eruptions may assume have just been reported here. In one case, during the taking of the bromides for some of the symptoms of the climacteric there developed on the face and neck a series of half-spherical nodules, some of them as large as a walnut, and smaller nodules near the margins of the hair. The surface of these nodules was uneven, granular-looking, excoriated, and with a marked tendency to bleeding. The fully developed clinical picture was exactly that of mycosis fungoides. The diagnostic difference lay in the more rapid development of the lesions in the drug eruption, the preliminary stage of erythema being a very short one. In the other case the use of antipyrin, and not in very large doses, was followed on a number of occasions by an erythematous spot an inch or more in diameter, in the right abdominal region. No other cutaneous lesions on any part of the body could be found, though they were carefully looked for. This single symptom was always preceded by an itchy feeling in the anterior abdominal region, extending around to both sides, but limited to the width of a belt.

Here in Berlin one seldom sees malaria. There is scarcely any of the disease in this part of Germany, and what there is occurs in patients who have contracted the disease in other lands. Recurrent neuralgias are, however, not so rare. A neuralgia that returns almost at a definite time every day, or sometimes every second day, or even at longer intervals, yet regularly, is not very uncommon. In a malarial region these would be set down at once as malarial. Here there can

be no question of their being that, yet they are often promptly relieved by quinine. This naturally causes a reversion to the thought of malaria once more, but there is absolutely no reason for it. The cases have been carefully examined just with this object in view, of deciding whether by any possibility there was a malarial element in the cases, but none could be found. It would seem either that the tonic effect of the quinine makes itself felt at once upon the functional disturbance of the sensory nerves, or that, as the old physiological therapeutists believed, there is an absolute anti-periodic effect in quinine which has been allowed to drop out of sight for the present, because the germicidal rôle of the drug in killing the plasmodium malarie has been supposed to be its only effect.

The thirteenth edition of Professor Ewald's book on "General and Special Prescription of Drugs" has just appeared, and is of interest as giving the newer drugs, even the proprietary preparations with their dosage, and their claims to therapeutic attention. The department of organo-therapeutic remedies mentions no less than forty of these preparations that are now on the market—extracts from every organ in the body. For some of them claims are made that far outstrip the wildest therapeutic dreams of the medieval panacea compounders. One very practical firm whose philanthropic aspirations for the relief of long-suffering humanity, especially in certain distinctively *fin-de-siècle* needs, are very evident, has no less than seven testicular preparations for sale. There is dried, powdered bull's testicle, then testinum (dose three to five grains), testidinum (a milder preparation), orchidinum, and sequardinum, besides two supposedly chemical equivalents for testicular extract, representing the active principles of seminal fluid.

Professor Posner's method of testing organo-therapeutic preparations by means of the Ehrlich tri-acid stain, though only in its period of probation, promises to be of distinct help to the practitioner and the dispenser, in enabling them to decide whether preparations really contain and how much they contain of the tissue extracts of various organs. Various tissues and their products seem to give specific characteristic reactions with these stains, and it is hoped that further study will develop the technique of this testing method so as to make it scientifically exact.

Meantime, there is no doubt that certain of the organo-therapeutic remedies are giv-

ing promising results. There is a prominent gynecological clinic here in which oophorin has given excellent results for the nervous symptoms of the climacteric, both the natural one and the anticipated change of life after the removal of the ovaries. Not long ago, in a report to the Berlin Medical Society, Dr. Saalfeld claimed to have got excellent results from it in certain of the skin diseases that develop about the climacteric—the rosacea of cheeks and nose, the obstinate eczemas that sometimes develop at this period, the prurigo and lichenoid eruptions that are met with. Later experience seems to show that oophorin influences favorably the acne and comedones of puberty. In these, where the results are so directly under the eyes, one might think that suggestion did not play a rôle; but it must be simply tried out, I suppose.

Instead of the ordinary incisions around either or both malleoli in arthrectomy at the ankle, some surgeons now employ the Pirogoff incision from malleolus to malleolus, passing underneath the heel. The arthrectomy can be made very completely in this way, and diseased material, judged of by sight as well as touch, can be very thoroughly eradicated. The parts may be better adapted to each other so as to give a useful limb and disposed to heal sooner, as not so much space is left after the removal of necrosed tissues to be filled up at first by blood clot with all its dangers of infection, and later by the slow process of granulations, before the wound is healed entirely. The scar beneath the heel will be of some inconvenience in walking afterwards, but most of this may be obviated by a groove in the heel of the shoe, which will have to be specially made anyhow, and the advantages during and after the operation more than offset this single disadvantage.

#### HONEY POISONING.

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I notice in your issue of February 15 that your correspondent, C. D. Voorhees, M.D., mentions a case of poisoning by honey. I have not a copy of Xenophon's *Anabasis* at hand, but I believe that in the last book of that work there is a detailed account of the sufferings of some of the Greek troops who partook of honey shortly after their arrival on the shores of the Euxine. In that case the poisonous agent was probably the "thorn-apple" (*Datura Stramonium*). I have myself seen boys seriously affected after eating the

honeycomb of the bumblebee (*Bombus Terestrus* and *Bombus Lucorum*). This occurred in England, in the county of Nottingham, where the foxglove is a common wild flower, very much affected by the bumblebees. The symptoms were vomiting, violent purging, and pain in the abdomen. The pupils of the eyes were widely dilated, and the pulse irregular and feeble. It has always been an enigma to me how the larvæ of these insects can eat honey derived from such plants as aconite, belladonna and digitalis with absolute impunity, when a very small quantity of the same honey produces marked toxic effects on the human subject.

In Nova Scotia we have very few poisonous plants which bear flowers, consequently poisoning by honey is unknown; but in England it is not at all an uncommon thing for children who have rifled a bumblebee's nest to be affected in the manner I have described. Trusting that I have not trespassed too much on your space, believe me,

Yours truly,

EDMUND JENNER, Apothecary.

SHERBROOKE, NOVA SCOTIA.

\* \*

To the Editor of the THERAPEUTIC GAZETTE.

SIR: I wrote you last week in reference to an article on poisonous honey, and since writing I find that the passage I alluded to occurs in Xenophon's *Anabasis*, Lib. iv, cap. xx, ad xxii. Freely translated the chapters run somewhat as follows: "But the beehives were very numerous there, and those of the soldiers who partook of the combs lost all their senses, and vomited, and it passed through them, purging them. . . . Now those who only ate a little were much like drunken men, but those who had eaten much resembled madmen and those who are about to die. . . . And it seemed in the army as if a rout had taken place, but on the following day they recovered their senses at about the hour they were taken ill, and none of them died; and on the third or fourth day they were recovered as if from taking medicine."

Ainsworth attributes this poisoning to honey gathered from the *Nerium Oleander*; other authorities to the *Datura Stramonium*.

I must apologize for troubling you with a second note on the subject. To my mind it is an interesting one, and I was glad to be able to find the passage in question.

Yours truly,

EDMUND JENNER, Apothecary.

### *THE ADDRESS IN SURGERY—STATE MEDICAL SOCIETY OF PENNSYLVANIA, 1898.*

By W. L. ESTES, M.D.,

Director and Physician and Surgeon-in-Chief of St. Luke's Hospital, South Bethlehem, Pennsylvania.

"Surgery has reached its zenith, and no advances of any value or magnitude may be expected in the future." This remark, said to have been made by a distinguished English surgeon ten years ago, seems ludicrous indeed in reviewing the work done in surgery during the last year alone. This work is so

considerable that I shall not, in the short time allotted to this address, attempt to give more than a sketch of a part of it, and then draw some conclusions which I trust may receive the indorsement of this Society, the members of which are known to be thoughtful students of medical progress and are accustomed to note the trend of scientific endeavors.

The brilliant operation of Schlatter, of Zurich, in successfully removing the whole stomach from a human being, stands perhaps foremost amongst the achievements of the year. As an exhibition of perfection in surgical technique it is remarkable even in this day of asepsis; as a contribution to the physi-

ology of digestion it is more valuable, however. While I do not believe it should set aside conclusively many deductions founded upon Dr. Beaumont's classical experiments on the healthy stomach of Alexis St. Martin, it gives us most important suggestions with reference to the proper status of the stomach, and the unthought-of possibilities of intestinal digestion. This vicarious intestinal assumption of gastric function in Dr. Schlatter's patient was reached only after a long and very gradual process, as the history of the case shows. The stomach of the old woman had at the time of operation been reduced to a small cavity with thick indurated walls; every vestige of glandular tissue was choked by the cancer, so that its sole function at the time of the operation, and probably for some time previously, had been simply to serve as an imperfect passageway for the food into the intestines. What little digestion had been possible was done by the intestines; the stomach was not only the seat of the poison-producing neoplasm, but was entirely cut out of the physiology of digestion. Surgeons who wish to repeat Schlatter's operation should bear this in mind. They ought also to remember that Schlatter's case was unique in that while the whole stomach was involved, the neighboring glands and omentum were not implicated, and the stomach was still freely movable and unattached by adhesions. To find these conditions combined in the same patient must be exceedingly rare.

Another notable instance of ablation and the marvelous adaptability of the gastrointestinal tract was the case of Shepherd.\* In extirpating a thirteen-pound fibromyoma of the mesentery Shepherd was obliged by dense adhesions to remove seven feet and eight inches of the small intestine of a man, who not only made a prompt recovery, but rapidly gained in weight afterwards. Equally remarkable was the operation of Mr. Frederick Treves† in removing the whole descending colon and rectum from a child who had idiopathic dilatation of the colon. Colotomy having failed to relieve the child, about eight months after this operation Mr. Treves did the second operation, which consisted in exsecting the whole colon from its flexure in the left hypochondrium, and the rectum, and then bringing the end of the transverse colon down to the anus and suturing it there.

The result was a complete relief of all the symptoms and a happy recovery of the child.

Hepatic and renal surgery have had a great impetus during the last year. Mayo Robson in England, and Langé, Senn, Halsted, Murphy, and Fenger in this country, have done most excellent work in cholelithiasis, while the labors of Kelly, Weir, Fenger, Gerster and others have done much in advancing the technique of renal surgery.

The impetus given by Kelly in this country, and by Pawlik on the Continent, to ureteral catheterization has led to routine examination of kidneys and ureter separately, and has made it possible to diagnose so surely that many brilliant operations on the ureter and kidneys have been performed. The future promises much for this line of work, and this will result in saving many kidneys and lives.

Besides this most excellent work, Kelly has inaugurated, with the help of Noble and a few other conservative men, an era of conservatism in gynecology. These surgeons now enucleate uterine fibroids or myomata without extirpating the organ itself; they recommend the enucleation of tumors of the broad ligament without sacrificing the ovaries, and even treating puerperal septic metritis without sacrificing the uterus in many cases.

Kelly's demonstration of the possibility of the air-distention method for cystoscopic examinations of the bladders of men is also of great importance.

Dr. J. B. Murphy has shown that it is quite possible to unite divided blood-vessels, and to repair torn vessels without obliterating their lumen or interrupting permanently the flow of blood through them, and he has thus made it possible to preserve important organs or members in case of accidental injury to their principal vessels.

The employment of skiagraphy, which promised much, has been shown to be of limited application, and while most useful in a *restricted employment*, the variability of tubes and currents, to say nothing of the plates used, makes it very difficult to lay down any very helpful and certain rules for the general use of the *x*-rays. Besides, the very disagreeable burns which have resulted from too long exposures indicate that photographic investigations ought in their mechanical parts to be entrusted to a limited number of experts, with fixed, properly tested, and well known apparatus. The fluoroscope, however, is a most valuable agent in employing *x*-rays, even to unskilful operators, and with a little practise it will render fruitful results.

\* *Montreal Medical Journal*, December, 1897.

† *Lancet*, Jan. 29, 1898.

The addition of formaldehyde to the sterilizing armamentarium has proved a valuable acquisition. For sterilizing knives and edged instruments generally (by its vapor) it seems almost an ideal agent; and it will perhaps soon divide honors with dry heat and steam for the sterilization of dressings.

The recrudescence of the very important discussion of how best to sterilize and prepare the hands for aseptic operations has resulted in the adoption very generally of some form of glove. The ideal glove material has yet to be discovered, but thin rubber gloves seem to have the best indorsement at present.

Schleich's general anesthetic mixture, which at first seemed to promise much, has not received the indorsement of American surgeons. In an experience of thirty-eight cases the writer has found that while anesthesia is easier as a rule, and cyanosis is not as common as with ether, vomiting, and especially late vomiting, is just as common and more distressing.

Dr. Willy Meyer in a recent letter published in the *Medical Record* of April 22, 1898, called attention to some investigations made by Dr. Weidig at his (Dr. Meyer's) suggestion, which showed that the ordinary Schleich's mixtures are really *mixtures* and not genuine solutions. The chloroform, petrolic ether, and sulphuric ether partly combine; no free chloroform could be found, but in each of the three solutions free sulphuric ether in varying proportions was found. Dr. Meyer also mentions the fact that Meltzer, who investigated the physiologic effect of pure petrolic ether for him, found that it acts as a tetanizing agent on animals. It may prove not to be the innocent diluent that Schleich believed it was. The mixtures should therefore be used with great caution.

Traumatic surgery has received scant consideration during the last year, and indeed for many years surgical investigations have been confined almost wholly to pathologic surgery. The distinction between "general surgery" and "gynecologic surgery" will possibly soon disappear and the two be merged, but there is gradually developing another special branch of surgery, which may be called "traumatic" surgery. In times of peace this specialty will belong chiefly to surgeons connected with railway, mine and mill hospitals. It is a great pity that this class of surgeons, on account of excessive work and modesty, has not given the profession the

product of its labors and experience in well considered, systematic and comprehensive monographs. The present "little unpleasantness" with Spain may serve to give a fresh impetus to acute surgery, and in the next few years traumatic surgery may again rank amongst the foremost endeavors of our progressive age. It is a great mistake to believe that the "last word has been said" in traumatic surgery. Antisepsis and asepsis have done marvels for conservative attempts, and in lowering the general death-rate after injuries. Of very great importance, in this branch of surgery, is the fact that acute anemia is the dominant factor in ordinary surgical shock. The writer in urging this doctrine about ten years ago gave certain comparative statistics from his own work to emphasize his point. In 1894, in a monograph entitled "A Contribution to the Study of Modern Amputations,"\* this doctrine was again brought forward, and it was shown that by practise founded upon it the mortality-rate in a series of 180 single major amputations (which included seven hip-joint amputations with only one death) was reduced to 2.77 per cent. against his former rate of 7.89 per cent in 114 cases; the double synchronous amputations in twenty-five cases was reduced to 12 per cent. mortality against 46.25 per cent. in thirteen cases after the old practise. Since the publication of the foregoing statistics he has had eighty-four single major amputations and two deaths, a mortality rate of 2.38 per cent., and seventeen multiple amputations and two deaths—11.7 per cent. mortality. In writing some years ago on the mortality-rate of modern amputations the writer stated that he believed the results of the single major amputations ought to be as good as those of the average ovariectomy operations. It seems he has finally realized this result. The argument for the method—if one can call it a method—is that as observation shows by far the majority of deaths after modern amputations occur within forty-eight hours after operation from exhaustion or shock, and as this so-called shock is a condition brought about by acute anemia (great loss of blood), it is had surgery to operate upon a person reduced almost to a moribund condition, when by careful antisepsis and the employment of elastic constriction *over the crushed tissues* no evil is likely to result for thirty or forty hours; and during this time, by the employment of active stimula-

\**Medical Record*, Nov. 3, 1894.

tion by strychnine and saline enemata, the patient may again have his vessels filled by blood and be brought to a condition which will bear a major operation.

The subject in acute or traumatic surgery which has received some commensurate consideration during the last year is fractures. This renewed discussion is probably due to the interest given the subject by the employment of x-rays and the comparative accuracy with which the friends of the patient as well as the surgeon may now determine how well the bone has been "set." In this field the writer predicts that radiographs are likely to be disturbing factors as well as useful instruments, and that they will multiply suits for malpractice and damages until a long series of investigations and observations shall prove that it is the exception and not the rule for the surgeon to be able to make exact coaptation and retention of the bony fragments after a so-called simple fracture.

The general tendency of to-day is the simplification of apparatus and the allowance of more freedom of motion and locomotion in the treatment of fractures. Of far greater importance, however, is the gradually growing belief that the majority of so-called "simple fractures" are far from being so indeed, and that explorations by incision and adjustments of fragments by sight are not only justifiable, but in many instances *absolutely essential* for proper treatment. An accumulating array of instances has shown these incisions do not augment the danger when the operation is done with proper aseptic precautions, and that they markedly improve the results of treatment. The *open method* of treating fractures in proper cases is now not only the safe method, but *the proper and imperative method of handling many fractures*.

The most opportune and most suggestive paper of the year was the one read before the Practitioners' Society of New York by Dr. McBurney on "When to Operate." This is a vital question in surgery and one which in many cases is far from settled. This is also a question in which surgeons ought to strive to indoctrinate family practitioners, for upon them in many instances this matter bears most heavily. Many organs and members have been sacrificed, and many lives lost, because the medical man in charge had not made up his mind or did not know *when* to operate. The important discussion on Mr. Marmaduke Shield's paper on "Immunity and Latency after Operations for Cancer of

the Breast"\* before the Royal Medical and Chirurgical Society of England, by such men as Pearce Gould, Watson Cheyne, W. H. Bennett and Fred. Treves shows that the whole question of cancerous invasion, growth, and cure are far from being settled even in the most maturely thoughtful and progressive minds. It is generally conceded nowadays, however, that preceding what may be called the invasion of cancer there is a precancerous stage, and that cure may be confidently expected if the tumor be thoroughly removed during this first stage. This fact ought to be thoroughly established and be received by the whole profession as a matter of the most vital importance. Family physicians should be made to believe that an incipient tumor should at once be submitted to the judgment of a surgeon, and that it is criminal to allow a patient to wait until ulceration or enlarged lymphatic glands declare the growth to be malignant. These pathognomonic signs also declare in many instances the death sentence of the unfortunate patient; they indicate that an extensive operation must be done, and the chances of recurrence at this time are greater than those of thorough eradication.

The removal of benign tumors ought also to be done as early as possible. Constant irritation, growth under pressure, or some dyscrasia of the patient, operate to make simple papillomata, fibroids, and adenomata take on sarcomatous (myxomatous) degenerations, and the border lands are so close that it is rarely ever safe to permit these tumors to develop as they will. It is far simpler, easier and safer to remove these tumors in their very early growth, and it should be done.

The danger of general tubercular infection from a single focus of invasion is too little appreciated by physicians. The persistent enlargement of lymphatic glands, especially about the necks of children, those of diathetic parents especially, should receive early attention, and the knife ought to be used before they break down and suppurate. Inflammations involving the bones of diathetic children, especially a condition suggesting an osteomyelitis, require early and radical operations. Many bones and limbs may thus be saved.

Nowadays intestinal obstruction from any cause, but especially the so-called mechanical ones and those from herniæ, should not be allowed to go on until a "typhoid" condi-

\*Lancet, Feb. 26, 1898.

tion and fecal vomiting indicate that profound septicemia and gangrene of the gut have taken place. Dr. Fred Kammerer, of New York, has called attention recently to a sign which nearly every surgeon of much experience has noticed, namely, that circumscribed peristalsis which is apparent to the sight at a very much distended point of the abdomen is indicative of complete obstruction. When this sign is observed with the other ordinary signs and symptoms of obstruction no time should be lost in performing an operation.

One would suppose that the much written of subject, appendicitis, had been so thoroughly discussed that little remains to be said on the matter of *when to operate*, and yet I dare say it is the experience of nearly every surgeon in active practise to see the cardinal rules neglected nearly every week. It is so well established that unless a case of appendicitis improves in forty-eight hours an operation is imperative, one is astonished to find so many cases allowed to suffer, and in many instances to die, because this rule is neglected or not known. Furthermore, the very important rule that an operation between attacks ought to be performed after a recurring attack of appendicitis of even a mild (so-called catarrhal) type is entirely too often neglected.

Recent work in renal surgery has shown the great good of early operative exploration and removal of calculi from the pelvis of the kidney. As soon as persistent or recurring pain, and microscopic and chemical examination of the urine, obtained separately by ureteral catheterization, have determined the probable presence of a stone in the kidney, an early removal of the stone will save the organ and restore the patient to health. It is of vital importance to remove a tubercular kidney as soon as the diagnosis can be made and the other kidney determined to be healthy.

Later teaching and clinical experience show the great importance of early operation in obstruction of the bile-ducts—especially the common duct. To wait for persistent jaundice, with frequent rigors, high temperature, and frequent vomiting before determining to operate exposes the patient to fatal septicemia and complicates the operation by inflammatory adhesions, besides the great danger of perforation and general septic peritonitis.

I might continue these instances beyond your patience to hear. I trust I have said enough, however, to suggest to you the very

great importance of recognizing the proper time for operating and how vital it is in many instances not only to *know* this, but to faithfully and firmly practise it. There are a great many conditions unfortunately which remain still in doubt; to the study of these surgeons should now give more attention. In order to know when to operate in any given case it is necessary to fully understand and to appreciate the pathology of the disease or traumatism as well as its clinical history; this feature of surgical investigation is too much neglected, especially in our country.

A recent notice of Stephen Paget's book on John Hunter, which appeared in the *Philadelphia Medical Journal*,\* very aptly sums up what seems to me the lesson to be learned from a review of the year in surgery. It says: "The lesson of Hunter's life was never more needed than to-day, when mechanical conceptions of surgery are so dominant and when technic has so largely replaced pathology." Improved technique has unquestionably widened the bounds of surgery and opened up vistas which to the daring and pushing surgeon seem well-nigh illimitable. The field of the general surgeon is encompassing that formerly sacred to the gynecologist, and now encroaches upon the domain formerly given over wholly to the physician. Are we not going a little too fast? Empirical precedents and undigested observation and experience do not furnish stable groundwork for lasting scientific facts. It seems to me we are in grave danger of outrunning physiologic and pathologic investigations in many surgical attempts. It is time "to cast an anchor to the windward" and wait for proper observations and the careful working out of our present location and bearings. Surgeons, of the United States especially, very much need more laboratories and fewer clinics. Besides the prevalence of "mechanical conceptions of surgery," another serious matter is that the *furor* for operating and the lust for extirpations have taken fast hold upon us. The surgeon who cannot enumerate his cases of organs removed by scores is a beginner indeed, and has but reached the stage where he must rush into print with a new device or "an improved method" for a pusher on the high road leading to his century count! Radicalism has been rampant; it is high time painstaking, thoughtful and scientific conservatism should have a fair chance.

\**Philadelphia Medical Journal*, March 26, 1898.

*A STATISTICAL STUDY OF INTUSSUSCEPTION IN CHILDREN, BASED ON UNREPORTED CASES; TOGETHER WITH THE REPORT OF A SUCCESSFUL OPERATIVE CASE.*

BY EDWARD MARTIN, M.D.,

Surgeon to Philadelphia, Howard and St. Agnes Hospitals

Cases of intussusception are perhaps best classified under Raffinesque's system as ultra-acute, death taking place in the first twenty-four hours; acute, terminating between the first and seventh day; and subacute, lasting two weeks or upward. Invagination may be enteric, involving the small intestine only, or ileocæcal, the ileum and cæcum, together with the valve, being turned into the colon; ileocolic, the ileum prolapsing through the ileocæcal valve, the latter retaining its proper position till secondary changes—it, together with the cæcum, is more or less displaced; colic, the invagination involving the colon only; and rectal, the seat of trouble being situated entirely within the rectum. Usually the upper segment of gut is received into the lower, but in Leichtenstern's 593 cases the reverse of this condition obtained in 1.5 per cent.

A retrograde intussusception secondary to the descending invagination is not so infrequent. In these cases the intussusceptum is surrounded by five layers of gut. This is probably due to a folding upon itself of the loose intestines and is said to occur only in the colon. It should be remembered that the intussusception may be double or triple.

Of many predisposing causes of intussusception, intestinal trauma (263 cases out of 593), polyp, especially that incident to a sudden jar or jolt, gastro-enteritis, and the straining incident to constipation, should take first rank.

The direct cause of chief importance is an irregularity in the nervous mechanism of the intestines which allows of a sudden spasmodic contraction of a portion of the bowel, while its adjoining conjunction may be entirely relaxed. This will apparently account for the intussusception of agony not rarely encountered in the course of post-mortem examination, and developed probably either during or immediately after the death struggle. These invaginations are often multiple, are limited in extent, and show no inflammatory changes.

The fact that obstructive invagination occurs in children, is associated with colic, is observed after abdominal injuries, and some-

times follows gastro-enteritis or typhoid fever, would all strongly suggest as probable causative factors disordered innervation.

Nothnagel studied this question from an experimental standpoint. By means of a faradic current he actively stimulated a small portion of the bowel; at the point of stimulation the bowel contracted firmly and often slight temporary retrograde intussusception was produced at the relaxed portion of the bowel, which was not influenced by the electric current, slipping down somewhat from above the seat of contraction. From immediately below the seat of firm contraction the bowel ascended in the form of a sheath, which progressively increased until the stimulation was removed, when nervous control being regained the intussusception underwent spontaneous resolution. Nothnagel further asserted that stimulation of the bowel above the intussusception is without effect, but that if an electric current or any sufficient stimulus be applied below this point the parts are promptly restored to their normal condition by the ascending contraction.

These experimental findings would be of very great value could they be corroborated.

Dr. Hare and myself some years ago made a great many experiments on dogs on the lines laid down by Nothnagel. We promptly produced the firm, ring-like contraction of the bowel, to which the current was applied, but observed no attempt at invagination. The stimulation was applied by two cells attached to a Dubois Reymond coil, which was drawn out to twenty on the scale. The segment of bowel stimulated was not upwards of a quarter of an inch in width. The current was used in all strengths and produced a local spasm so pronounced as to make the area stimulated resemble cartilage both in appearance and touch, yet we never observed the faintest attempt at either ascending or descending invagination.

As to the frequency of occurrence, in a total of 1652 cases of intestinal obstruction, hernia excluded, collected by Leichtenstern and Bryant, 657, or approximately forty per cent., were due to intussusception.

Of Leichtenstern's 593 cases, 131 occurred before the age of twelve months, and the great majority of these in the fourth, fifth, and sixth months. This finding is corroborated by the statistics of Smith, Hanson, and Pitts.

Bull and Coley in summing up the reports for 1894 collected twenty-seven cases of intussusception—nineteen males and eight

females. The average age, excluding two children over two years of age, was eight and one-third months.

All statistics show that intussusception in children is most frequent about the sixth month, that after the fifth year it becomes comparatively rare, until the fortieth or fiftieth year, when it again increases in frequency of occurrence. In the first year of life the ileocæcal form is more common than the combined forms of all the others, the ileal invagination being exceedingly rare. When the ileum is involved it is usually in its lower segment. Intussusception of the colon is commonly found in the sigmoid flexure.

The acute form in infants is characterized by a painful onset, commonly in the ileocæcal or umbilical region. After a few hours the child frequently becomes dull and lethargic, with paroxysms of pain and restlessness. Vomiting is practically constantly continuous till shortly before death, and is rarely feculent. It is proportionate to the completeness of obstruction and does not afford the slightest index in its time of onset as to the seat of invagination. Blood-stained mucous evacuations are perhaps more constant and typical than any other single symptom. Of 108 cases of invagination occurring in the first year of life, this symptom was absent in but four. Proportionate to the amount of obstruction the fecal contents of the evacuations diminish, mucus and blood forming the greater portion. This discharge is commonly very offensive. Not infrequently there is diarrhea and evacuation of blood-stained feces throughout the entire attack. This is, however, rather characteristic of the chronic than of the acute form.

Tumor, the most diagnostic symptom of invagination, was felt in sixty-three per cent. of Leichtenstern's infantile cases. It was usually found in the left iliac region either by abdominal palpation or better still by combined palpation, the index-finger of the right hand being passed deeply into the rectum, while the fingers of the left hand palpate through the abdominal parietes. In ileal invagination this tumor may be absent. It is commonly sausage-shaped and varies in size and consistency from time to time, becoming hard, knotty and plainly perceptible during a paroxysm of pain and shortly after eluding the most careful search. Tenesmus is a symptom sufficiently common to be of diagnostic import. It is present in complete obstruction, and according to Brinton is especially

characteristic of ileocæcal and colon invaginations.

A further sign of some importance, although it occurs in other forms of intestinal obstruction, is a patulous condition of the anus, due to paralysis, and according to Leichtenstern dependent upon invagination of the descending colon and rectum. This is not noted in the ileum invaginations.

These symptoms would seem to be fairly characteristic, but in the absence of tumor it must be acknowledged that unless the others are all typically developed they will not enable the practitioner to distinguish between a severe case of enteritis and one of intussusception.

There can be no question that many cases of intussusception are not recognized. I am not aware of any reported cases showing that an error in the other direction—*i.e.*, the mistaking of a severe case of enteritis or colitis—has resulted in an operation for the reduction of supposed invagination. It is probable that examination under ether will show a tumor in practically all cases.

The prognosis of intussusception is extremely grave. Leichtenstern places the general mortality as seventy-three per cent. In seventy-three cases collected by Hare and myself in 1889 the mortality was ninety per cent. In the first year of life the mortality is very high, reaching eighty per cent., death commonly occurring between the fourth and seventh days. Bull and Coley found the mortality of twenty-seven cases collected in one year was thirty-seven per cent.

Wiggin states that intussusception occurring in young infants is a hopeless condition when left to Nature's care: ninety-eight per cent. terminating fatally when the immediate and remote effects of sloughing are considered.

The methods of treatment to be considered are massage, rectal injections, and reduction of invagination through an abdominal opening. Though massage has successful cases credited to it, it is at best a blind and usually futile measure and one likely to do more harm than good. Injections are, however, of incontestable value, and in so far as statistical study goes have been nearly as successful as has abdominal section.

The injection may be of air or of liquid. Injections of air are less easily controlled, and are lacking in the mechanical weight of a liquid injection, this latter factor being often an important adjunct in the reduction of an invagination. Injections of liquid,

aside from direct surgical intervention, afford the most efficient means of reducing invagination.

The liquid of choice should be normal salt solution at a temperature of 102° F. The temperature is important. As a result of experimentation Hare and I found that by a pressure of one and a half pounds warm normal saline solution could be passed from the rectum into the stomach of a dog without interfering with its vital functions in the slightest degree, and without being followed by any impairment in digestion or general health. A cold solution produced marked and immediate shock, was much slower in going through, and left the dog sick for some hours. The hot injections at 116° F. caused death from heat-stroke.

As to the method of giving a forced injection, the pathology of intussusception teaches us that disinvagination becomes more difficult as time elapses from onset of symptoms, hence every hour diminishes the chances of success. When the invagination is less than forty-eight hours old, and in this time sloughing or marked weakening of the bowel is extremely rare, the child should be wrapped in cotton, ether should be given to its full surgical extent, producing complete relaxation of the muscular system, and by means of a fountain syringe normal saline solution at a temperature of 105° should be allowed to flow into the rectum at the rate of about four ounces a minute under a pressure of not over two pounds to the inch, obtained by elevating the irrigating bag four feet, the liquid being retained by a shoulder upon the injection pipe, readily made by wrapping it with a narrow bandage. During this injection the child should be inverted, the abdomen should be kneaded, the operator endeavoring to grasp the sausage-shaped tumor in its lower part and to squeeze it out by a motion much like that made in milking a cow.

This treatment should be continued for not less than fifteen nor more than thirty minutes, the bag being gradually raised until a pressure not greater than four pounds is produced. The pressure of the fluid should be gradual, steady, and progressive. The first effect of the injection is to occasion muscular spasm. This yields completely to steady pressure. The quantity of fluid used should be limited. Mole has shown that the infantile colon will be completely filled by a pint and a half. I believe that in some cases twice this quantity can be used without danger, but since we can never be sure that the

bowel is perfectly healthy, it is perhaps wisest to limit the quantity to a quart. As to the pressure employed I have been able to subject the healthy gut of a child, removed from the body, to a pressure of five pounds, without causing injury to the peritoneal coat. When the bowel is supported by parietes and surrounding viscera it is evident it could readily stand considerably greater pressure. In the light of other experiments and in consideration of the fact that in intussusception the gut is never quite healthy, four pounds should be the extreme limit, a patient trial being first made of an elevation of three or four feet (1½ to 2 pounds).

This trial at forced reduction must be thorough and final. There must be no idea that it is to be repeated with more care and attention to detail. Every hour of delay makes the efforts at reduction less likely to succeed. If it fails immediate operation should be undertaken. I believe it would be wise before making this attempt at disinvagination to complete all preparations for section and to proceed at once to this measure when a careful trial of the injection has proven abortive.

Success from injection will be shown by disappearance of tumor and by sudden flow of the contents of the irrigating vessel, which should be of glass and graduated.

In operating the median incision is probably the one of choice. It is to be carried up above the umbilicus in case of need. The invagination will be found immediately and without difficulty. The first effort should be directed toward accomplishing disinvagination. This is best accomplished by stripping back the intussusciens by a milking motion practised with both hands; traction upon the intussusceptum, excepting an amount just sufficient to afford support, is unjustifiable. A probe slipped between the entering and returning layers may loosen adhesions so that the intussusciens may be stripped inch by inch.

If reduction can be accomplished in this way the question as to so fixing the bowel that the intussusception cannot be reproduced may be wisely considered.

This may be accomplished by a stitch securing the gut to the parietal peritoneum, though the efficacy or even necessity for this procedure is certainly questionable. If the intussusception cannot be reduced a longitudinal slit of the intestines, delivering of the intussusceptum, transfixing with pins, the removal of the portion distal to the pins and

suture of the divided ends, is the method recommended; the sutured ends being then returned into the lumen of the gut, and longitudinal incision being closed by Lembert suture. The operation is completed by a row of Lembert sutures uniting the intussusciens to the intussusceptum at a point where the latter enters the former.

This sometimes implies a large opening into the intussusciens, the delivery and handling of an extensive sloughing, thoroughly infected mass, with a somewhat tedious suture at a period of the operation when time is of vital importance. I believe this, which is Maunsell's operation, might be wisely modified by applying a continuous Lembert suture, uniting the intussusciens and intussusceptum at the point of junction; a one inch incision should then be made an inch below this circular suture through the convex border of the intussusciens. A ligature should be passed around the intussusceptum at a point above the area of sloughing and gangrene, should be tied tightly, and the whole mass below should be cut away. The ligature with the divided bowel ends should be drawn through a small opening, transfixed with pins and sutures as in Maunsell's operation. In this case the difficulties and dangers incident to delivery and proper care of the sloughing intussusceptum might be avoided.

Intussusception is usually regarded as a common affection of childhood, but I have been particularly impressed with its extreme rarity. As far as I have been able to discover but one case has ever been treated at the Children's Hospital of Philadelphia. Examinations of the records of other institutions reveal a similar paucity of material.

Eight hundred personal letters sent out with stamped and directed return envelope brought me only fifty-four cases. The great majority of these letters were answered. Men of the widest experience, both in medicine, surgery, and in pediatrics, stated that they had never seen a case. My purpose in sending these letters was not primarily to demonstrate the rarity of intussusception, but rather to demonstrate its true mortality. There is a natural tendency to report only successful cases, and believing that this rendered entirely inaccurate statistics compiled from general records, I started a personal investigation, confidently expecting to have several hundred cases from which could be drawn reliable conclusions. The form in which the inquiries were sent out is as follows:

#### INTUSSUSCEPTION IN CHILDREN UNDER TWELVE YEARS.

Seen by Dr..... In personal practise..... In consultation..... Age of patients..... Cause of intussusception (polyp?)..... Symptoms—Tumor..... Passage of bloody mucus..... Tenesmus..... Vomiting..... Intense pain..... Treatment—Medical..... Result..... Mechanical (Injection of air..... water..... Massage.....) Result..... Period elapsing from first symptom to mechanical treatment..... Treatment—Operative (disinvagination through abdominal opening.....) Result..... Resection..... Result..... Seat of invagination..... Amount of bowel resected..... Method of joining intestines..... Period elapsing from the first symptom to the time of operation..... Results of autopsies.....

Further details not covered by the above headings will be gladly received, such as recovery with passage of slough, etc.

It is worthy of note that in addition to personal letters, through the courtesy of the *THERAPEUTIC GAZETTE*, *Journal of the American Medical Association*, the *Boston Medical and Surgical Journal*, the *Medical News*, and a number of other medical journals in various parts of the country, I am indebted for some extremely interesting cases. The small number tabulated as a result of this inquiry shows the rarity of the affection. (See Table.)

The average age of the patients thus collected, representing hitherto unpublished cases of intussusception in infants, was thirty-four months. Much larger published statistics seem to show that the age at which the affection is most common is about six months. The youngest patient on my list was two days old (case reported by Dr. Barton C. Hirst). The next youngest was four weeks old (reported by Dr. Walter Chrystie, of Bryn Mawr, Pa.).

Tumor was present in forty cases, absent in seven, not mentioned in twelve. Excluding the last figures it was observed in eighty-five per cent. of cases. Muco-sanguineous discharges were present in forty-six cases, absent in thirteen—seventy-eight per cent. Tenesmus was present in forty-three cases, absent in eight, not mentioned in eight—85.6 per cent. Vomiting was present in fifty-seven cases, absent in eight—86.4 per cent. Pain was present in forty-five, absent in nine, not mentioned in five—86.5 per cent.

It will be noted that all these symptoms were present in a large majority of cases, but that the least constant one was the discharge of blood-stained mucus.

As to the gross results of treatment, of four cases subjected to treatment other than mechanical, one recovered by sloughing. Fifty-three were treated by air or water injections; of these thirteen were subsequently subjected to celiotomy. Of the forty not

operated on, but treated by water or air injections, seventeen recovered, a mortality of 42.5 per cent. It is noteworthy that one case subjected to water injection and unimproved was cured by subsequent injection of air.

Of the fifteen cases operated on two recovered, a mortality of 86.6 per cent.

As to the causes of invagination, polyp is mentioned in three cases, stricture in one case, foreign body in one case, jarring in two cases, entero-colitis in eight cases, constipation in one case, and coughing in four cases. It is worthy of note that trauma seems to be an important factor in the production of invagination, and that in some instances bouncing of the child, such as is commonly done in play, has been stated by the physician to be the direct cause.

The two cases which I personally observed both occurred in the practise of Dr. C. J. Hoban. One was hyperacute in type, exhibited all the characteristic symptoms, excepting tumor, and perished practically before any active treatment could be instituted. At the time I saw this child it was pulseless, with cold limbs, pallid face, sunken eyes, and evidently moribund. The time for surgical intervention was past, and indeed the child died five minutes after we left the house.

The second case occurred in the person of a child seven months old. There was no history of previous illness. The child was suddenly seized with acute pain, which caused it to scream violently; it passed blood-stained stools and vomited persistently. Tumor was felt in the left iliac fossa and also on digital examination in the rectum. Dr. Hoban, seeing the nature of the affection, sent the child to the Howard Hospital, where four hours after the onset of symptoms I made one conscientious and thorough attempt at reduction by water enema. The child was etherized; the bag was elevated to a height of eight feet, pressure being maintained for fifteen minutes. The tumor apparently disappeared. The enema was followed by a copious blood-stained mucous discharge. On digital examination by the rectum the invagination could no longer be felt. By bimanual palpation, however, a distinct tumor was plainly perceptible in the left iliac region. The pulse was 160, the respirations 40. Operation was at once decided upon and performed Monday morning, December 5, 1896. The invagination was an ileocolic type, six inches of the small

intestine and the ascending and transverse colon forming the intussusceptum. Reduction first seemed difficult, but peeling back the intussusciens, the intussusception being slightly separated, the gut rolled into its normal position. This process having once been fairly started, it was completed without difficulty. The intestine was in fairly good condition, the peritoneum being eroded under one or two spots, presenting a raw, intensely congested, bruised appearance. The incision was four inches long and extended obliquely forward from the left toward the right side, the umbilicus being at about its upper third. It was closed by through-and-through suture of silkworm-gut, as the child's condition was such that speed was necessary. The operation occupied twenty minutes. The following day the pulse ran to 180, the temperature to 103½°. There were, however, three free loose bowel movements, containing very little mucus and blood, the passage of a large quantity of wind, and after the second movement the pulse fell to 138. The child was stimulated and treated on general principles, being given castor oil, and calomel was required. On the seventh day I removed the stitches from the perfectly clean wound, carefully reinforcing by surgeon's plaster as each thread was taken out. A large, clean dressing was applied over the abdomen. The whole was held in place by two broad strips of plaster designed to lessen tension upon the womb. The mother of the child celebrated the removal of the stitches by giving it an unusually heavy meal, which caused vomiting. During these violent vomiting motions the whole wound burst open, and some hours later I found lying beneath the dressing and between it and the abdominal skin the greater portion of the small and large intestines. The child was again etherized, the intestines were replaced, and a double row of sutures was applied. This second operation was followed by no shock, nor was there any inflammatory reaction. The stitches were left in place for eighteen days. On their removal there was no tendency to further opening of the wound, and the child has subsequently been perfectly well, with the exception of one sharp colic attack. It is now about eighteen months since intervention.

The only other case of successful surgical intervention is one operated on by Dr. J. B. Murphy. In his case eighteen hours had elapsed between the development of symptoms and operation.

In considering these figures—representing the result of computation from a tabulation of unpublished cases, mainly infantile—it is noteworthy that the gross mortality of Leichtenstern's non-surgical cases is much greater than in my table—*i.e.*, 73 per cent. as contrasted to 42.5 per cent. The mortality of the operative cases which I have been able to collect is, however, somewhat higher than that computed from any hitherto published tables. Thus Holt (*Diseases of Infancy and Childhood*) notes that the mortality of seventy-two operative cases was 80.5 per cent. Schramm computes the mortality at 70.4 per cent.; Ashhurst, on a basis of 133 cases, as 76.5 per cent.; Treves, 33 cases, as 72.7 per cent.; Wiggin, on a basis of 74 cases, 58.1 per cent.; Barker, on a basis of 73 cases, 82 per cent.

It is evident that the mortality of the cases operated on is greater than that of the cases subjected to mechanical treatment, and that so long as operation is reserved for desperate cases, and as the final resort after hours or days of fruitless medicinal and mechanical treatment, only by the most ingenious juggling with statistics can the surgeon find support for intervention in the study of tabulations. It is none the less perfectly clear that were intervention instituted at once on the first failure of one thorough effort at reduction under an anesthetic, the now high mortality of the affection (probably over fifty per cent.) would be markedly lowered.

The conclusions which seem justifiable from a study of infantile intussusception are:

1. The affection is a rare one in any one locality or in any individual experience. The general impression among medical men to the effect that it is common has not the support of either hospital records, vital statistics, or personal inquiry.

2. Gastro-enteritis is a distinct predisposing factor.

3. The diagnosis of infantile intussusception from severe entero-colitis in the absence of tumor may be quite impossible. Fortunately tumor is present in over eighty per cent. of cases. Often it has not been found because search has not been made for it. Sudden and violent onset, frequent small blood-stained mucous passages, and the rapid minimizing of the quantity of feces passed, would suggest intussusception. Under such circumstances palpation should be practised, one finger being passed into the rectum, the other fingers of the other hand being applied to the abdominal surface. When there is

reasonable doubt the child should be relaxed by ether before such examination is made. The tumor is not necessarily on the left side, being found in a small percentage of cases to the right.

4. The first attempt at reduction should be thorough and final. This is most likely to be successful if practised upon the thoroughly anesthetized child. The method of choice is the slow injection of normal saline solution by gravity at a temperature of about 102° F. and under a pressure of at first four feet—not greater than eight feet after ten to fifteen minutes. Inversion and gentle massage aid in accomplishing reduction.

5. Reduction by injection should not be attempted in hyperacute cases which have lasted more than twenty-four hours, nor in acute cases which have lasted twice this time. Immediate operation is safer for such cases.

6. Reduction by injection having failed, there should be immediate recourse to celiotomy and direct disinvagination, or if this procedure is impossible, ligation and resection of the adherent and sloughing mass practised through a small incision through the intussusciens, and union of the divided bowel as in the Maunsell method. The portion of the gut cut away may be delivered through the anus.

#### *THE SURGICAL TREATMENT OF COMMON DEFORMITIES OF THE FACE.\**

BY JOHN B. ROBERTS, M.D.,

Professor of Surgery in the Woman's Medical College of Pennsylvania.

The effect of facial disfigurement upon the earning capacity of an individual is generally recognized. Those desiring positions as household servants, nurses and salesmen are rejected at once if unsightliness of feature is at all conspicuous; and they may be refused by hypercritical employers when the want of comeliness is not great.

Facial blemishes sufficient to produce these results are likely to be subjected to surgical treatment in most urban communities; there the popular mind has become familiar with the resources and safety of surgical science. In more sparsely settled districts, however, and in cities of less advanced culture, men and women are frequently seen with most hideous deformities, which could easily be removed or greatly lessened by simple and innocuous surgical procedures.

The effect of physical deformity upon the mental characteristics of the afflicted individual is often most deleterious. The timidity and consequent social ostracism, due to even very slight facial blemishes, are only fully realized by those whose professional activities bring them into contact with such cases.

Because of these influences upon the character and earning capacity of the patient, surgical interference is to be adopted for the relief of even slight deformities, which in other parts of the body would be deemed unworthy of attention.

Much more can be done to relieve these conditions than is generally appreciated. They require, however, the knowledge usually possessed by the general surgeon to be supplemented by the special training and manipulative skill of the ophthalmologist, rhinologist, and oral specialist. It is probable that the limited attention given to the correction of these facial defects is largely due to the differentiation of specialism. The operator who knows how to relieve an ectropion or to properly adjust an artificial eye, for example, may have had no experience in correcting deformities of the nose. He is an oculist alone, and therefore not accustomed to osteoplastic operations upon the nose and jaws. Again, the work may not be undertaken, or not completely done, because the surgeon is familiar with amputations at the hip-joint and extirpation of the uterus, but has never split up a canaliculus, or sawed an intranasal spur associated with a crooked nose.

The partition of the facial structures to the various specialists has had, I am sure, a deleterious influence upon the development, and proper realization of the resources, of what may be called the cosmetic surgery of the face. This branch of surgery is very interesting, but requires for its successful performance an artistic appreciation of proportions, a delicate touch, and the specialized and small instruments of the oculist, aurist, and rhinologist. These must be added to the operative experience of the general surgeon, who is accustomed to large wounds and resections of bone; and who is not startled by hemorrhage from the internal maxillary or carotid arteries.

The operator can approach these cases with a great deal of confidence; because the very abundant blood-supply of the face makes anemic gangrene of flaps unusual, the bleeding which occurs is so accessible to operative hemostasis, and the shock of opera-

\*Read before the Medical Society of the State of Pennsylvania, May 18, 1898.

tion is in most cases unimportant. It only needs to have the operation well planned and neatly and artistically performed to insure success. The worse the deformity the greater as a rule is the satisfaction of the patient; because the improvement is so manifest, even when the final result leaves a condition that in normal faces would be considered a disfigurement. It is the patient who has very little deviation from the normal, and who has become morbidly sensitive, that is apt to be dissatisfied with the result of the operative treatment. In these cases the mental condition must be treated both before and after operation. The line of treatment is that adapted to neuroses in other departments of medicine. Pleasant mental occupation, distraction from one's self, nerve tonics and the usual hygienic accompaniments are needed in these as in other neurasthenic patients. Surgeons are too apt to overlook these valuable adjuncts to a perfect operative recovery.

An important point to insist upon is the necessity for repeated operative procedures. The patient as well as the surgeon should understand that it is often impossible to obtain a perfect restoration by one operation. It is frequently necessary to wait until Nature has absorbed the inflammatory exudate and caused shrinking of the flaps before determining what is the next step to be taken to further improve the appearance. Haste at this stage often leads to unnecessary operations or to unwise selection of lines of incision. At first a crude restoration of parts may be all that can with propriety be done.

The methods used in plastic or reparative surgery of the face cannot be recapitulated in the time assigned me by the committee, and need not be, since they are those well known to the profession. Skin-grafting, sliding and interpolation of flaps, osteoplastic operations, the introduction of non absorbable substances, the construction of artificial organs such as eyes and teeth, and the adjustment of celluloid or metallic substitutes for areas of lost tissue, are employed. The selection and adaptation of these expedients must vary with the condition to be remedied and be left to the individual judgment and experience of the operator.

The conditions which can be improved by surgical and prosthetic treatment are numerous and varied. A catalogue of these would include nearly every disease of the differentiated facial structures. The field of cosmetic surgery of the face is almost limitless. It

extends from tattooing a white scar on the cornea to the construction of an acceptable lower jaw or nose; from making a pair of ears comely to straightening a crooked nose or curing a salivary fistula; from removing a few freckles to remedying the distortion due to extensive burn or gunshot wound.

The object of this paper is to call attention to a greatly neglected branch of surgery; to urge the general surgeon to cultivate the thoughtfulness and manipulative skill of the specialist; and to make the profession and public familiar with the great relief that can readily be given to a large class of unhappy patients—patients who are permitted to go through life handicapped because they know not the relief accessible to them.

*MULTIPLE INTUSSUSCEPTIONS OF THE  
SO-CALLED POST-MORTEM TYPE, OB-  
SERVED DURING LAPAROTOMY  
FOR A PENETRATING STAB-  
WOUND OF THE AB-  
DOMEN.*

---

BY ROBERT G. LE CONTE, M.D.,  
Philadelphia.

---

Jose C., aged 9½ years, was admitted to the Pennsylvania Hospital on August 11, 1897, with a penetrating stab-wound of the abdomen, caused by the blade of a penknife. The wound was situated about two inches to the left of the median line, a little below the level of the umbilicus, and was a third of an inch long on the skin surface. A plug of omentum protruded. The abdomen was opened in the left semilunar line, and the peritoneal wound was found to be more than double the length of the skin wound. Some artery had been severed in the abdominal wall, probably the deep epigastric or one of its large muscular branches, as the surrounding muscular tissue was distended with clot and there was a considerable hemorrhage into the peritoneal cavity. On searching the intestine for a wound, a direct intussusception an inch long was found about the middle of the small gut, and two or three feet lower down two more were found, one direct and the other retrograde, each about three-fourths of an inch long, while the sheath or intussusciens was probably two inches in length.

These intussusceptions resembled closely in appearance the kind so frequently observed at post-mortem examinations. There

was no sign of inflammation, no congestion or change of color in the gut or mesentery. The peritoneal coat was normal in appearance, and reduction was accomplished with very light traction.

Treves in his work on Intestinal Obstruction divides invaginations into two great forms, according to the circumstances of their origin: (1) the common or obstructive intussusception, and (2) the intussusception of the dying. The latter form depends upon certain irregular peristaltic movements which may be conceived to occur during the act of dying, either from the changes in the circulation, or from irregular stimulations of the (vagus) nerves. They also may form many hours after death, which is well illustrated in a case reported by Ruhrah (*Archives of Pediatrics*, April, 1896). While making an autopsy twenty hours after death on the body of an infant, he saw an intussusception of the ileum form, and on handling the intestines, other portions of the ileum and jejunum began to invaginate themselves, so that in a few moments the entire small gut had become a mass of intussusceptions, varying from five to ten centimeters in length.

The invaginations of the moribund differ from obstructive intussusceptions in that they are always small, free from congestion or inflammation, are often multiple, direct as well as retrograde in character, and are reduced by very slight traction. This case presented all these peculiarities and none of the obstructive type. In searching for the probable cause of these intussusceptions, three present themselves as possible: (1) The mechanical injury to the abdomen (the blow of a knife); (2) the considerable hemorrhage that had taken place into the abdominal cavity may have caused some change in the intestinal circulation; and (3) the opening of the abdomen and handling of the intestine while searching for a wound. The latter seems to me the most probable cause.

The recovery of the patient was uneventful, except that on two occasions he complained for a few hours of severe abdominal cramps, which were sudden in onset, and not associated with diarrhea or constipation. Treves has suggested that some of the sudden colicky attacks in children may have as their anatomical basis a series of temporary invaginations of the bowel, and it is possible to conceive that in this case one or more of these invaginations may have temporarily recurred.

## SOME EXPERIENCES IN SURGICAL GYNECOLOGY.

BY ANNA M. FULLERTON, M.D.,

Clinical Professor of Gynecology, Woman's Medical College, Pennsylvania.

Successful work in surgical gynecology requires the careful solution of certain problems which constitute most important factors in the attainment of the desired result.

1. The first and most important point in the management of a gynecological case is the making of a correct diagnosis. Until gynecology, as one of the branches of medical science, is given due prominence in the curriculum of medical schools, both in the didactic and practical courses, the generality of the medical profession must frequently fall into grave error by failing to recognize the nature of many internal maladies from which their patients may suffer. The vague terms "pelvic peritonitis," "pelvic inflammation," or even "inflammation of the bowels," have been employed to cover a class of symptoms arising from very different causes. The history of an attack is not sufficient clue to the nature of the malady that may exist. Careful palpation of the pelvic contents by an experienced finger alone can enable one to determine whether the uterus or its appendages or surrounding structures are the offending members in any given case.

2. A diagnosis being made, the next point to determine is the question of treatment—whether it shall be operative or non-operative. Many important considerations must enter into the formation of one's decision on this point. Certain classes of cases, such as ectopic gestations, accumulations of pus in the pelvis, etc., will not brook delay. Prompt and efficient action is indicated. Even here, however, it is fruitless to snatch a patient from a threatened danger only to plunge her into greater danger by subjecting her to the performance of a grave operation by an unskilled hand, or under conditions which disregard the requirements of aseptic surgery.

3. The third consideration, therefore, concerns the choice of operative methods, including the preparation of the patient, the conduct of the operation, and the after-treatment of the case.

4. If we desire to keep our mortality list low we must give due heed to contraindications to operation that may exist in the general condition of the patient, or in marked disease of any other organ which may affect the result. So often do we find some disease

of other organs in patients requiring operative treatment that the weighing of a patient's chances in any given case often requires a very nice judgment.

Temporary conditions of acute pelvic inflammation, due to non-septic causes, we find to respond readily as a rule to the ordinary palliative measures for allaying inflammation, such as the use of salines, rest in bed, counter-irritation, etc. If properly treated they are apt to get well, without leaving any permanent lesion behind them. Palliative measures, when conditions warrant them, should therefore have a fair trial before operative procedures are resorted to.

When the history of a case and careful and intelligent examination prove a pelvic malady to be an immediate menace to the life of a patient or a source of persistent ill health and recurring disease, it is, I believe, poor practise to waste time in prolonged palliative treatment when an exploratory abdominal incision can clear up any doubt and prepare the way for more effective management.

A brief summary of the operative work recently done in my own service at the Woman's Hospital of Philadelphia may better illustrate some of the points I desire to make. The bacteriological examinations required were kindly made for me by Dr. Lydia Rabinowitsch, bacteriologist to the hospital; the pathological examinations by Dr. Marie K. Formad, its pathologist. I am indebted also for much valuable aid in the management of my cases to my assistants—Dr. Marie Formad, Dr. Frances Hatchette, and Dr. Adelaide M. Underwood. The interest and assistance of Dr. Ella B. Everett, chief resident, also deserve appreciative acknowledgment.

Celiotomies performed were as follows:

CASE I.—Femoral hernia; radical operation; recovery.

CASE II.—Double pyosalpinx; retroverted adherent uterus; repeated attacks of pelvic peritonitis. Bilateral removal of appendages; recovery. A small sinus existed for a time at the site of the drainage tube, which closed later. The patient was brought to the hospital suffering from an acute attack of pelvic inflammation, the result of leakage from the tubes. Bacteriological examination showed the pus to contain gonococci.

CASE III.—Ovarian cystoma. Removal of appendages of right side; recovery. This patient had been operated upon the year before for a similar condition of the ap-

pendages of the left side. The right ovary did not then seem sufficiently diseased to warrant removal, especially as the patient desired to retain it if possible; a few cysts contained in it were punctured at the time. The rapid development of trouble in this case illustrates the proneness of the remaining appendages to take on disease.

CASE IV.—Pedunculated uterine fibroid, with chronic disease of appendages. Hysteromyomectomy, bilateral removal of appendages, hysterorrhaphy; recovery. The existence of but the one growth in this case seemed to render it unnecessary to prolong the operation sufficiently to remove the entire uterus.

CASE V.—Double pyosalpinx. Bilateral removal of appendages, resection of ureter, uretero-cystostomy; recovery. The patient had suffered from repeated attacks of pelvic inflammation. She had been confined to her bed for two months previous to her admission to the hospital from a recent attack of peritonitis. During the operation adhesions of the pelvic viscera to surrounding structures were found to be numerous and dense. In the necessary enucleation of the appendages the right ureter was inadvertently severed. It was found on examination to offer that rather rare form of anomaly, a double ureter. Fortunately the division occurred so low down in the pelvis that it was possible to implant the distal extremities of the divided ureter into the upper portion of the bladder. The convalescence was without event.

CASE VI.—Retroflexed adherent uterus; sclerotic ovaries. Separation of adhesions, removal of appendages, hysterorrhaphy; recovery. This patient had passed the menopause for some years. She was in a state of nervous demoralization in consequence of pelvic pain. The ovaries were very small and as hard as little pebbles, owing to calcareous degeneration. Relief from pain was complete, following the operation, and the patient has again been enabled to take up with satisfaction the work she had given up as housekeeper in a girls' boarding-school.

CASE VII.—Fibrous thickening of posterior wall of the uterus; chronic salpingitis and ovaritis. Bilateral removal of appendages. As this patient was of feeble constitution, time was not taken for the removal of the uterus.

CASE VIII.—Wandering fibroid spleen; splenectomy; recovery. All the symptoms of this case, together with the clinical history, pointed to a probable ectopic gestation—sup-

pression of menses, recurrent colicky pains; sanious discharge from the uterus, with the expulsion of what her physician had taken for a cast of the uterus; colostrum in the breasts. A mass in the left side of the pelvis crowded the uterus to the right. To my surprise the mass proved to be a greatly engorged and enlarged spleen, with a long, twisted pedicle, its vessels filled with thrombi. The tumor was removed and the patient has continued in good health ever since.

CASE IX.—Double hydrosalpinx. Bilateral removal of the appendages; recovery.

CASE X.—Fibroid uterus; hysterectomy; recovery. Numerous adhesions existed in this case—the result of previous inflammatory attacks.

CASE XI.—Retroverted adherent uterus; chronic disease of appendages. Bilateral removal of appendages; separation of adhesions; recovery.

CASE XII.—Diseased adherent uterus; hysterectomy; recovery. This case is one among others that have come under my notice which would seem to illustrate the desirability of doing very radical operations for removal of the pelvic organs when affected by advanced gonorrheal diseases. The operation performed in this instance was the third abdominal operation done by myself for this patient. The first was for the removal of the appendages; the second, for separation of the uterus from new adhesions, especially to the bowels, and fixation of the organ by suture to the anterior abdominal wall; the third, a separation again from adhesions and entire removal of the uterus.

CASE XIII.—Fibroid tumor of uterus; hysterectomy; recovery. The convalescence of this patient afforded an interesting and unusual complication. She had been a native of the West Indies and had suffered repeatedly from the various tropical fevers, which had probably resulted in producing organic changes of the liver. Hence, following her etherization, she suffered from frequent vomiting of a dark, moss-green, frothy mucus. No treatment seemed to be of any avail in checking it, except that some respite was obtained by washing out of the stomach. There was little fever, the pulse was not rapid, nor was there any abdominal tympany. The abdomen had been kept well strapped by adhesive plaster to prevent strain from interfering with the union of the wound. On the eighth day after operation, the stomach being quieted, and the wound having apparently

healed by first intention, the stitches were removed. A day or two later a severe vomiting attack occurred, the wound opened up, and the intestines were extruded from it. I cleansed and replaced them and kept the wound packed with sterile gauze until it closed up by granulation.

CASE XIV.—Carcinoma of the uterus. Hysterectomy; decease of patient on third day from exhaustion due to chronic sepsis. The autopsy in this case showed a perfect condition of the site of the operation. It was found, however, that the patient had an amyloid liver with cancerous deposits throughout its substance. There were also large masses of fungous growths over the liver and parietal peritoneum in the upper portion of the abdomen. Had this condition been recognized before operation, the patient would not have been operated upon.

CASE XV.—Cysts of the broad ligament with cystic disease of the ovaries and chronic salpingitis. Bilateral removal of the appendages; recovery. This operation was done for a patient whose mind was affected. Though the patient became quieter and more manageable after operation, this procedure has not served to restore her mind. The conditions which existed, however, demanded operation apart from the effect which they might be supposed to have upon the mental state.

CASE XVI.—Advanced tubercular disease of uterine appendages and peritoneum. Bilateral removal of appendages, with the evacuation of nearly three gallons of free liquid from the abdominal cavity. The prognosis in this case was bad from the nature and extent of the malady discovered. Within three months after her return to her home, paracentesis abdominis was done twice for a reaccumulation of the fluid, and the patient shortly afterward succumbed to the progress of the disease.

CASE XVII.—Procidentia uteri; varicosity of broad ligaments; chronic disease of appendages. Bilateral removal of appendages; hysterorrhaphy; recovery. For the extreme relaxation of the vagina a Le Fort operation for its closure was done later.

CASE XVIII.—Intraligamentous multilocular cystoma of immense size filling both the abdomen and pelvis. Patient was sixty-nine years of age. Death from secondary shock. The patient had carried the tumor for thirty years, during which time she had been a constant sufferer, spending much of her time in hospitals. The recent rapid growth of the

mass had greatly increased her sufferings, causing retention of urine and edema of the vulva and lower limbs. The patient therefore determined to have the operation done at all risks. I had some doubt of the patient's ability to pass through so trying an operative procedure, and therefore had her heart examined previously by a specialist, who pronounced it a "senile heart," but found no evidence of organic disease. He thought that with care an anesthetic might be safely given. The operation proved to be a formidable one, dense adhesions existing. There was very little blood lost, yet the patient was badly shocked. She rallied, however, for a time, but again relapsed and died of exhaustion. No more striking illustration could be afforded of the evils of delay in the removal of tumors. Thirty years of suffering and a fatal termination might have been avoided had the operation been undertaken earlier in the patient's history.

CASE XIX.—Suppurating ovarian cystoma with tuberculous disease of the appendages, and disseminated miliary tubercle of the entire visceral and parietal peritoneum. Removal of cystoma and bilateral removal of appendages; recovery. Many bowel adhesions existed in this case, requiring considerable stitching of the bowel to protect the points weakened by separation of adhesions. Had there not been so much pus which it was necessary to remove, I should have felt tempted to close the abdomen without completing the operation. The patient was thoroughly septic when operated upon. She made a brave struggle for life, however, and recovered with a small fistula at the site of the drainage tube, which at times discharged fecal matter. The patient desired me to operate again for closure of the fistula, but knowing the extensive involvement of all the abdominal organs in tubercular disease, I did not feel warranted in encouraging her to go through with another operation.

CASE XX.—Multilocular uterine fibroids. Hysterectomy; recovery. One of the growths in this case involved the posterior uterine wall in such a way as to cause much distress from pressure. Complete relief was experienced immediately after the operation.

CASE XXI.—Ventral hernia, the result of a celiotomy for removal of pus tubes. Recovery.

CASE XXII.—Retroflexed uterus. Intra-peritoneal shortening of the round ligaments for correction of position of uterus; recovery.

CASE XXIII.—Multilocular cyst of right

ovary of large size; removal; recovery. Just preceding the operation the patient had suffered from a sharp attack of peritonitis, the result of an injury. The adhesions resulting from this were quite extensive.

CASE XXIV.—Tubercular pyosalpinx. Bilateral removal of the appendages; recovery. This patient when she came to see me at my office was wearing ichthyol ointment over her abdomen for the severe pain from which she suffered, and taking electrical treatment *per vaginam*. The existence of tubercle bacilli in the pus from the tubes was demonstrated by bacteriological examination.

CASE XXV.—Pelvic abscess, the result probably of an attempt at criminal abortion; rupture of left tube; patient *in extremis* from septic absorption. Evacuation of abscess and removal of gangrenous appendages of left side. Death from sepsis third day after operation.

CASE XXVI.—Retroflexion of uterus. Intra-peritoneal shortening of round ligaments; recovery.

CASE XXVII.—Chronic disease of appendages; bilateral removal; recovery. In this case I had done Alexander's operation for correction in position of a retroflexed uterus some time before. The patient suffered greatly from dysmenorrhea, which it was thus demonstrated was due to the condition of the appendages rather than the abnormal position of the uterus.

CASE XXVIII.—Chronic salpingitis and ovaritis; hematoma of ovaries. Bilateral removal of appendages; recovery.

CASE XXIX.—Tubercular ascites. Exploratory celiotomy; evacuation of fluid; lavage of abdominal cavity; recovery. The visceral and parietal peritoneum as well as the contents of the pelvis were studded with miliary tubercles.

CASE XXX.—Chronic salpingitis and ovaritis. Bilateral removal of appendages; recovery.

CASE XXXI.—Fibroid tumor of uterus (hemorrhagic). Hysterectomy; recovery.

CASE XXXII.—Chronic disease of the appendages. Bilateral removal; recovery.

CASE XXXIII.—Tubercular pyosalpinx; rupture of tube. Bilateral removal of appendages; recovery.

CASE XXXIV.—Gonorrheal pyosalpinx and ovarian suppuration. Bilateral removal of appendages; recovery. The extreme distention of the tubes with pus in this case accounted for the paroxysmal pains, strongly simulating those of ectopic gestation, from

which the patient suffered for two months before I saw her.

CASE XXXV.—Hemorrhagic uterine fibroid. Hysterectomy; recovery. This patient when brought to the hospital was so ill that she was considered an unfit case for operation. She had been so reduced by hemorrhage that upon examination of the blood a marked condition of leucocytosis was noted. As the effect possibly of pressure from the tumor, an irritating diarrhea existed which further exhausted her. She was unable to void urine owing to obstruction of the urethra, and had to be catheterized at intervals. After tonic treatment and careful feeding for several weeks she was prepared to pass through her trying operation with safety.

CASE XXXVI.—Double pyosalpinx and ovarian abscesses; subperitoneal uterine fibroid. Myomectomy and bilateral removal of appendages; recovery. This patient also was extremely ill when admitted to the hospital, already suffering from pus absorption.

CASE XXXVII.—Fibroid uterus; chronic disease of appendages. Hysterectomy; recovery.

CASE XXXVIII.—Enlarged cystic ovary with hematoma. Unilateral removal of appendages. As this operation was done for a comparatively young woman I did not feel warranted in removing both ovaries. The condition of the one remaining was fairly good.

CASE XXXIX.—Hydrosalpinx, chronic ovaritis, and salpingitis; numerous adhesions, the result of repeated attacks of peritonitis. Bilateral removal of appendages; recovery.

CASE XL.—Uterine fibroid; hysterectomy; recovery.

The cases of celiotomy just enumerated included nine cases of hysterectomy, two of hystero-myomectomy, eight cases of removal of appendages for pyosalpinx, four for removal of cystic tumors, two celiotomies for tubercular peritonitis, two herniotomies, one splenectomy for wandering spleen, two cases for intraperitoneal shortening of the round ligaments, two operations for removal of appendages for hydrosalpinx. The remaining (eight) celiotomies were salpingo-oophorectomies for chronic disease of the appendages, attended with repeated attacks of peritonitis.

Other operations done during this period included two cases of vaginal hysterectomy; three exploratory incisions of the vaginal vault; two cases of vaginal puncture for

evacuation of inflammatory products in the broad ligament; six cases of amputation of the uterine cervix; four operations for shortening the round ligaments by Alexander's method; thirteen rectal operations, including six Whitehead's operations for hemorrhoids; one proctorrhaphy for prolapse of the bowel; the remaining operations for fissures, fistulæ, and ischio-rectal abscesses. Eight vesical and urethral operations were done; twelve trachelorrhaphies, twenty-five perineorrhaphies, and several other plastic operations upon the vagina for relaxation; four cases of excision of the breast; three cases of evacuation of breast abscesses. Several other minor operations were called for.

The three fatal cases in the entire list were those in which an error in judgment in estimating the strength of the patient, and a failure to appreciate the extent of the disease, were possibly partial factors in the defeat. All were desperate cases: the first, that of neglected intraligamentary cyst; the second, of disseminated carcinomatous disease; the third, of puerperal sepsis. The keener one's surgical sense becomes, the less frequently must such misfortunes overtake the operator.

123 S. 16TH ST., PHILADELPHIA.

*SOME REMARKS CONCERNING RECTAL AFFECTIONS, WITH ESPECIAL REFERENCE TO THE PHYSICAL EXPLORATION OF THE RECTUM.\**

---

BY LEWIS H. ADLER, JR., M.D.,  
Professor of Diseases of the Rectum, Philadelphia Polyclinic and College for Graduates in Medicine; Surgeon to the Charity Hospital and to the Out-patient Department of the Episcopal Hospital; Professor to the Professor of Anatomy, Medical Department of the University of Pennsylvania, Philadelphia, Pa.

---

There are some practitioners who think that the diagnosis of rectal diseases is attended by considerable difficulty, and that complicated apparatus is required in order to reach a positive conclusion. Such is not the case. Nor, on the other hand, is it true that any satisfactory opinion can be formed by a cursory and careless inspection of the anus and adjacent parts. It is due to such a method of examining that I have noted polypoid growths diagnosed as prolapse of the bowel, and fissure of the anus or irritable ulcer (a better name) unsuccessfully treated

---

\* Read at the meeting of the Medical Society of the State of Pennsylvania, held at Lancaster, Pa., May, 1898.

because of the presence of an undiscovered polypus. Likewise, persons affected with malignant stricture of the rectum being subjected to operation for the removal of coexisting hemorrhoids or of a fistula *in ano*, whilst the real trouble was undetected.

My object in presenting this paper is to detail the method which I employ in investigating cases of rectal disease and affections of the sigmoid flexure, and to lay special stress upon the necessity of making a thorough physical exploration of the bowel in every case of suspected rectal trouble.

All persons suffering from diseases of the rectum are much depressed and more or less nervous. This fact, combined with the natural restraint experienced in paying a first visit to a physician, should be realized by the examiner, and in order to aid such persons to recover their composure it is best to encourage them to give the history of the disease in all its details. Whilst this consumes time, the more important object is accomplished of securing the cooperation of the patient in the subsequent steps of the investigation, to wit, the digital exploration of the bowel, without which a positive diagnosis can never be made. These remarks are especially applicable to the treatment of females. Assent to a vaginal examination is much more readily obtained than is the consent to inspect the seat of rectal trouble.

After the patient has concluded the description of the ailment, then by a few well directed but not leading questions we may be able to complete the history. The following are the principal queries which may be asked with advantage:

*First, in reference to pain.*—Is there any pain? If so, of what character? Is it situated in the rectum? What is its relation to the act of defecation? Is it worse during an evacuation, shortly afterwards, or some time after the movement? Is itching, a sense of fullness or heat experienced?

*Second, regarding protrusion at the fundament.*—Is there any swelling or protrusion at the anus? Does this occur only at defecation, or is it independent of this act? Does the bowel bleed? Does it go back spontaneously, or has the patient to return it?

*Third, as to the presence of a discharge.*—Is there any discharge? If so, what is its nature (bloody, mucous, or purulent)? Is it offensive? Does it occur before or immediately after defecation, or is it independent of the action of the bowels?

*Fourth, as to the regularity of the action of*

*the bowels.*—Is there a daily movement, or does constipation or diarrhea exist? What is the character of the fecal evacuation, as to color, size, and consistence?

*Finally, the following general interrogations should be made.*—Does the patient cough, have night sweats, spit blood, or has there been a loss of flesh? What are the habits of life, especially with reference to the use of alcoholic liquors, tobacco, and indulgence in venery? Is there any specific history? Lastly, inquire as to any hereditary tendency to rectal trouble, malignant disease, kidney, liver or heart affection. In women inquire into the condition of the sexual organs, etc. Whenever the idea of any operative procedure is entertained, the urine should be examined and a thorough physical inspection of the patient made.

Having obtained the subjective symptoms and being satisfied as to the existence of rectal disease, we proceed to confirm the provisional diagnosis, and to obtain positive information upon which to base the prognosis and to guide the treatment, by making a thorough local examination of the anus and adjacent parts, including the rectum. If possible the patient should have the bowel emptied by an enema immediately before an examination is attempted. In the case of female patients especially, the neglect of this will often render a thorough investigation impossible, without recourse to general anesthesia, owing to the patient's fear of an accident occurring, such as the escape of flatus. Under such circumstances I have known the sphincter muscles to be so tightly closed that the surgeon was frustrated in the attempt to explore the parts. When a specular examination is necessary—as in the investigation of the higher portions of the rectum, or of the sigmoid flexure—it is absolutely essential that the contents of the bowel be cleared out.

There are various postures in which this examination may be made. Some surgeons prefer the patient to lean over the back of an ordinary chair; others, to have them kneel upon a table with the head placed on the folded arms of the patient, by which means the buttocks are elevated and the intestines are allowed to gravitate from the seat of investigation; others, the lithotomy position; but for general use I think that the most comfortable as well as the most delicate posture for the patient, and that most convenient for the examiner, is for the patient to lie on a firm couch on the left side, the right

shoulder turned away from the surgeon, the left arm brought behind the body, and the right thigh well flexed upon the abdomen. In examining for the presence of strictures or growths situated above the lower four inches of the rectum, by directing the patient to stand and strain, the diseased part will be brought nearer to the anus, so that at least an inch more of the bowel may be explored than can be done when the patient assumes the usual position, even though directions be given to bear down.

Regarding light, either natural or artificial light may be used. I prefer the former. By means of a head-mirror—the operator sitting facing the light and the patient's back being from the same—the light may be concentrated upon any particular point requiring observation.

The instruments usually required are: A flexible probe, made of silver, useful for the exploration of fistulous tracks; an exploring needle, or a small trocar, by means of which can be ascertained the nature of the contents of any swelling or fluid collection met with in these parts; Dr. Howard A. Kelly's short and long proctoscope, and sigmoidoscope; sponge-holders; basins; and possibly a hypodermic syringe, with a flexible silver cannula attached, which is useful in detecting whether a fistulous track be complete or otherwise. Plenty of towels and cotton should be on hand.

Everything being in readiness for the examination, we now proceed to inspect the condition of the external parts. On separating the buttocks, the orifice of the anus will come into view. The radiating folds should be separated by the fingers, and cracks, excoriations and fissures should be looked for. External hemorrhoids will also be noted, if present. By passing the finger around the anus and making pressure, any induration that exists will be detected; this may be due to a fistula or an abscess. If the parts are covered with a discharge it should be wiped away and its source traced, as to whether it be from an external opening of a fistulous track, etc. Eruptions of any kind—eczematous, syphilitic, or otherwise—must also be noticed.

The next step is to make a digital examination of the interior of the rectum. It is by this means that the most important information is to be gleaned, and it is a procedure that should never be omitted in any case of presumed rectal trouble. Such an investigation is not a very pleasant one, either to the patient or to the practitioner, yet without it the physician needlessly sacrifices his repu-

tation and risks possibly the patient's life. It sometimes happens that a patient refuses to be examined. I recall the case of a woman who visited my office and who not only refused permission for an examination, but freely expressed her surprise at my making the request. In part this action was explained when she informed me that I was the fifteenth or sixteenth doctor she had consulted, and that it was the first time that any such procedure had been suggested. I politely informed her that the investigation was particularly needful in her case and might be the means of preventing any further increase in the number of her medical advisers.

The method of making the examination is as follows: The nail of the index-finger being well trimmed and the finger lubricated with carbolized oil, which I prefer to vaselin or other similar substances, is introduced into the bowel by a slow boring motion, in a direction at first slightly forward. This should be done gradually, so as to allow the sphincters time to relax; if attempted too hurriedly or in too forcible a manner, spasm of the muscles will to a certainty be induced. As the finger enters, the condition of the sphincters is to be noted. The strength, measured by the power of resistance, will be found to vary greatly in different people. In the aged or debilitated it is apt to be very weak, and just the reverse in the strong and healthy. In persons of a specially nervous tendency, and in cases of irritable ulcer of the anus, a contraction may be met with, which, owing to the pain, will render an examination impossible without the use of an anesthetic.

The finger should now be passed its full length up the bowel unless an obstruction exists, and by instructing the patient to bear down forcibly the rectum can be explored for a considerable distance. Additional length may be gained by passing the other fingers of the examining hand backward along the intergluteal groove, instead of closing them in the palm, as is generally done, and pressing the knuckles against the soft parts. The knuckles, in the latter procedure, prevent the full passage of the index-finger. In this manner about three and a half or four inches of the rectum may be explored, together with the prostate, the neck of the bladder, the uterus, the anterior surface of the coccyx, the lower part of the sacrum, the ovaries and tubes, and the broad ligament. With an exceptionally long finger it may be possible to feel the seminal vesicles and the vas deferens.

In making a rectal examination it must be

borne in mind that frequently two or more rectal diseases coexist, as for instance a polypoid growth complicating a fissure, or malignant disease existing with fistula and hemorrhoids, etc.

Malignant infiltration, or stricture, can be detected, if situated within reach. By sweeping the finger around the mucous membrane, its condition can be noted; a general smoothness and absence of the normal folds indicating atony. Ulceration may be recognized; and the attachment of polypi can be felt. In examining for a polypus, it is important that the finger be brought from above downward, as otherwise the growth may be pushed out of reach owing to the length of the pedicle, which is often considerably elongated. Fecal masses in the rectal pouch can be recognized without difficulty.

The finger is now to be partly withdrawn, passing the palmar surface around the entire surface of the mucous membrane as this is done, in order to note the existence of internal openings of fistulæ, the seat of ulcers, etc. As the outlet of the bowel is approached, internal piles may be perceived, but the fact should always be remembered that unless they are thickened by inflammatory changes they are extremely hard to recognize by the sense of touch; in point of fact, the sensation conveyed to the finger is more apt to deceive the surgeon than any other rectal trouble.

Mr. Chas. B. Ball states in his admirable treatise on "The Rectum and Anus, Their Diseases and Treatment," that he has frequently seen cases in which these growths, although scarcely appreciable to the touch, were found, upon ocular inspection after dilatation of the sphincters, to be of considerable size. This he claims is owing to the fact that they are so soft and movable that they closely resemble in feel the normal columns and folds of the mucous membrane.

*The Use of the Speculum*—In the large majority of rectal diseases, digital and ocular examination is sufficient for purposes of diagnosis, but for some cases the use of the speculum is a desirable adjunct. These instruments are made in a variety of forms. The speculum which I now commonly employ for diagnostic purposes is one of the several lengths of Kelly's tubes; the length of the tube selected depending on the portion of the bowel to be explored. Previous to being introduced into the rectum, the speculum should be warmed and then well lubricated. On inserting it into the anus it should be gently but slowly directed a little

forward and upward for a distance of about an inch, as if to pass from the perineum to the umbilicus, in order that it may follow the course of the anal canal; having reached this depth, which is somewhat greater in the male than in the opposite sex, the point should be inclined backward, first slightly and afterwards to a greater extent, until the instrument is fully in.

Should the interior view of the rectum be obstructed by blood, mucus, or feces, a mop of cotton attached to a holder made for the purpose should be used to cleanse the parts. With these instruments the interior of the rectum and the sigmoid flexure can be examined and the exact condition of affairs ascertained. Other forms of specula are furnished with blades or plates, which can be separated to the requisite extent by means of a screw attachment.

*The use of the rectal bougie* for diagnostic purposes I mention only to condemn. The introduction of these instruments is one of considerable difficulty and requires greater practise than the passage of a urethral catheter; the danger of perforation is greater, and the result of such an accident is very much more serious than in the urethra. In the one case a fatal peritonitis will likely be started, while in the other a false passage will probably be the sequence. The use of the Kelly tube has obviated the necessity of employing the bougie for the purpose of diagnosis.

*Rectal Eversion as a Means of Diagnosis.*—In examining the rectum in females, Dr. H. R. Stover, of Boston, has recommended eversion of the bowel by the finger placed into the vagina. This method is useful in women who have borne children, but not in the young and unmarried. A portion of the anterior wall may thus be exposed.

*The introduction of the hand* into the rectum is a procedure which may be a means of exploration open to the surgeon, but I am inclined to view the amount of information obtainable by its use hardly sufficient to warrant the practise.

*Exploration with a silver probe*, seven or eight inches in length, is of value in detecting blind external or internal and complete anal fistulæ. Being flexible it may be bent to any desired form.

*Injections of various fluids*, such as peroxide of hydrogen, a two-per-cent. solution of creolin, milk, or a weak iodine solution, often serve a useful purpose for detecting the internal opening of a fistulous track.

ADDRESS IN OBSTETRICS BEFORE THE  
PENNSYLVANIA STATE MEDICAL  
SOCIETY, MAY, 1898.

By S. S. TOWLER, M.D.,  
Marienville, Pa.

This address is from the standpoint of the general practitioner and the commonplace; from the standpoint of the general practitioner, not in that sense of antagonism to the specialist that is becoming an unfortunate feature in the profession—a feature that bodes no good and is to be deplored—but from the standpoint that the general practitioner is, notwithstanding numerous articles on his “decadence” and his “passing,” yet the most important, as he is the most numerous, personality in the science of medicine. From the very nature and complexity of the human organism it will be a “sorry day” for the unfortunate sick when there is an end to that individual known as the “family doctor.” There need be no fear, however, of this, as long as the profession has the sound sense to recognize, as they now do, that the best specialists are those trained as general practitioners. In using the word “specialist” throughout this paper, it is to be understood as referring to the specialist concerned in this subject—none other.

The line between obstetrical practise and gynecology is so narrow that, for the purposes of this paper, it is assumed that one includes the other. The specialist should be considered as the ally, friend and helpmate of the general practitioner. Any of the brethren who are not willing to act that part should be promptly dropped for one who will. The responsibility of the general practitioner does not end with the calling in of the specialist, and should not so end. The patient should still be his, and all his rights ought to be carefully considered and justly observed. There are specialists who are the soul of honor, who respect the trials, difficulties and position of the “family doctor;” men who come to his side anxious both for him and his patient; men who are willing to share with him the unfortunate issue, if so it be, as well as the success, if such be their happy lot. It is a pleasure to testify here and now that we do not have to go beyond the confines of this commonwealth to find them, nor outside of the membership of this Society. On the other hand, there is a class practising gynecology that general practitioners hate and ought to hate. It is that class whose clientage are brought in by

more or less sly advertising—by personal friends acting the part of runners, and meddlesome old women. This kind pose as a sort of “great wonder,” and, after exhibiting office specimens, make a variously executed examination, that fairly stuns the patient. After that comes the cut at the general practitioner. The woman may have had anywhere from one to ten children, but all the same, he calmly and impressively says, “I am sorry to say, Madam, that the physician who attended you last in confinement was ignorant of his duties. You have a bad, a very bad, terribly bad, rupture of the cervix” (rising inflection).

The chances are ten to one that the tear is an insignificant one (but the fee a large one), and that the little tear occurred in the first confinement, and not the last. His fault is not in saying there is a tear, if that *is* the condition, but in emphasizing it, for his own benefit, and the placing of a responsibility beyond his knowledge.

Yes! we hate that fellow with a vigor born of righteous indignation. Yet it is but fair to add that he would have made just as contemptible a general practitioner as he does a specialist. There is, however, a fair and honest field of opposition to any specialist that the general practitioner can and should enter into and enjoy; it is that sort of opposition that will, so far as in him lies, do his own work so well that the specialist will have no case through any *fault* of his.

This brings us to the subject from the standpoint of the commonplace. The great majority of deliveries are commonplace. They do fairly well with only neighborly help. This is a great comfort to the general practitioner, who consoles himself, on refusing to go on a charity call, with the thought that “she will get along all right anyhow.” At the same time, we all know that it is a sin and a shame for people of means to be running any risks at such a time. We like to warn them beforehand, to take no chances on old women and good luck. It may be the proper professional thing to vigorously damn the successors of “Sairy Gamp” and “Betsey Prig,” on account of their ignorance, dirtiness, and presumption; but it is just as well to remember that precisely the same results follow the carelessness and neglect of the educated physician. It is from this carelessness and neglect of the commonplace that the vast majority of calamities arise in obstetrical practise. One of the unfortunate features is that so many cases come to us

without any previous knowledge of their condition. The pregnant woman should be taught to report to the family physician as soon as she knows she is pregnant. It is not necessary for me to explain here in detail how much suffering would be saved and how many sad results would never occur if this practise was more common. The diagnosis of pregnancy is by no means always easy or certain. When there is a doubt, and the patient begins to show decline, prompt means should be taken to ascertain the actual condition. It may be tumor, extra-uterine pregnancy, cancer, tubercular peritonitis, hydatids, or some other abnormal and dangerous condition. It is due to the patient to find out. The way to find out is to send for the most competent medical man we know. If the patient is poor, it is proper to ask the poor authorities of town or county to assist in either bringing in the needed assistance or taking the patient to that assistance. There is neither right nor justice in refusing fair compensation to the medical attendant, while at the same time the butcher and baker are getting their pay. If the family are able to pay some compensation it ought to be required, but all of it ought not to go to the specialist. If he is the right kind of a man he will not expect it. An excellent plan in the poorer class of cases is to take advantage of the clinical lectures offered through a committee of this Society, and when you get your expert, rush in your doubtful cases. You will find more difficulty on the part of the patients than you will find kicking on the part of the specialist.

If circumstances permit—if the patient is close by and the surroundings suitable—the patient should, if an operation is needed, be operated on at home. The general practitioner who is not competent to take care of a patient after operation and instructions by his specialist ought to at once go and learn. If the circumstances are not in line with success, then she should be removed, preferably to a well-conducted hospital. There are cases, fortunately very rarely, when all the chance possible demands immediate operation. Expert skill may be at too great a distance to be secured in time. Under these circumstances the nearest and most competent surgeon should be called in, and, with the consent of the family, the operation performed. She is entitled to all the chance that available skill can give her. To this end we should use all means in our power to qualify ourselves for just such emergencies.

Yet always, when experienced skill can be obtained, it is imperative to obtain it. Skillful rapidity of operation may be the only salvation, and this cannot be obtained by the occasional operator. In the ordinary cases, too often, the vomiting of pregnancy is treated with various medicines, until the patient is losing strength mentally and physically. As soon as it is evident that relief is not being afforded, applications, preferably of tincture of iodine, should be applied directly to the os. Lightly tamponing the cervix with a strip of borated gauze is often effective when applications fail. Whatever means are used, if evidence of improvement is not soon manifest, new measures, carefully studied out, should be promptly used. Yet all the time, it is not to be forgotten that not all the nausea, perhaps none of it, is due to pregnancy, even though pregnancy exist. There are other organs in a woman besides the uterus—an exceedingly commonplace fact, too often forgotten or ignored. When all reasonable effort to control the vomiting has failed, it becomes the serious question of determining whether the attempt is to be made by feeding, stimulants, etc., to carry the woman to term or near term, or induce labor early. Is it not sound sense and good judgment to take the side of least risk to the patient? The time of least risk to her is certainly *not* when she has become a starved wreck of her former self. Yet we are advised, time and again, to carry her along as far as possible toward term in hope of a change. That line of "possible" is a danger line easily passed by even a largely experienced, but hopeful, practitioner. When induced labor is determined upon, and this should be settled in consultation with the nearest most competent medical man or woman, the condition of the patient must be considered as well as the method. In most cases a firm tampon of gauze in the cervix, followed by frequent douches of warm sterile water, will be all that is needed. A rubber bedpan with outflow tube, and a fountain syringe holding two or three quarts, make the procedure neither uncomfortable nor exhausting to the patient. Glycerin, injected into the cervix, the os covered with thin rubber protective to prevent immediate outflow, followed by a snug packing of the vaginal vault, with plain or borated gauze, is perhaps the next least dangerous method.

Whatever procedure is followed, thorough cleanliness and complete emptying of the uterus must be constantly kept in view.

Throughout the entire term of pregnancy, and especially in the last third, particular attention is to be paid to kidneys, bladder, and bowels. It requires frequent inquiries and imperative commands, on the part of the medical attendant, to obtain anything like proper attention to the bowels of either pregnant or non-pregnant women. In the last month of pregnancy it is a mistake to urge the woman to exercise freely. It is a period that demands rest, quiet movements, light meals of nourishing food, and abundant sleep. When time is up, and the practitioner is called, he should make it his special business to look thoroughly into the surroundings—the bed is to be made as clean as the possessions of the family will permit. The idea that “any old thing” will do until after completion of labor is a bad mistake, and yet a more common one than some suppose. The bed should be firm and the springs taken out. How much this simple procedure helps both patient and doctor only those who have tried it know. A little ingenuity puts the springs back again with little disturbance to the woman.

As to the person of the patient, we have been for some time past regaled with what the writers call “the obstetric toilet.” With some of these advisers the woman is to be put through a series of washings, scrubbing, douches, and packings, that puts to shame the necessary procedure of the rigid skilful gynecologist. On the other hand, we are told that all this is unnecessary. Both are wrong. In normal cases a good warm bath, and a vaginal douche of warm sterile water, is all that is necessary. It is never to be forgotten that the use of any solution that dries up, or tends to dry up, a natural healthy secretion is wrong. Diseased conditions are to be met promptly, but we are not to use drugs when drugs are not called for. The cleanliness of the practitioner is of as much or more importance than that of the patient. In the majority of cases infection is from without. If the attendant *knows* that there is nothing septic about him, then a good wash of arms and hands with hot water and good laundry soap, with proper attention to the nails, is all that is needed. There must be no doubt, however, of the prior cleanliness. If there is any doubt, then nothing short of thorough disinfection is to be used before any examination is made.

It is not long since the writer knew of a case in which the practitioner went directly from incising a septic abscess to attend a

primipara. The woman shortly after died from infection. Ignorance, some would say. Yet this man hangs on his office wall the diplomas of two of the nation's best medical universities. No! not ignorance, gentlemen, but unquestionably criminal negligence. In view of the records made in maternities, where cleanliness all around is the rule, the continuance of puerperal fevers, of more or less grave character, in general practise must be attributed more to carelessness than surroundings. Except in the cases of the degraded and very poor, a fair amount of cleanliness may be secured by careful attention and persistence. But just so long as one hugs to himself the hope and chance that each patient will get along as well as the majority do, will he take risks that, sooner or later, will land him and his patient in trouble.

When the examination is made, it is to be made thoroughly. We are not to wait until the head or other presenting part is jammed and wedged in the pelvis before we know that version is necessary; or a loop of six inches, more or less, is felt externally before we find we have a prolapsed cord; or half a dozen other abnormal conditions exist. Because pains are feeble, or “just a few in the back,” is no excuse for not promptly ascertaining the exact condition, as far as possible, at the first examination.

When forceps are to be used has taken up much time and ink, and yet the squabble in some journals goes on. On the one side, we have the man who would only wait an hour or two, and then apply. We have another set whose only conception of instrumental delivery is to hitch on and drag out. We have the solemn old gentleman, who poses as better than all of us, because he has practised forty years and never used them. Thank Heaven! we have also those doctors who are not only the salt of the profession, but almost “the salt of the earth”—doctors whose guide in this, as in all else they do, is sound common sense.

It is not the purpose of this paper to go into many details of any feature presented. It is one of the purposes, however, to point out that in the careless or reckless use of forceps we furnish the gynecologist with many a needless case. In too many instances the practitioner is in too much of a hurry. In these days of many doctors and much competition there arises the fear that during an absence some patient may get into a rival's office, and a quarter, more or less, be

lost forever. So in the haste to be wealthy one ceases to be wise. If a big dose of ergot does not hurry up the affair, one goes a pair of instruments. There are some simple things usually ignored in this haste. One is that forceps are not to be applied until the os is so dilated or dilatable that both head and forceps will emerge without stretching the part until tears result. There is no reference here to abnormal conditions, or even normal conditions, that make this sort of delivery impossible without some rupture; it is the undue haste that is condemned. Again, the ordinary forceps are not to be compared, as to either safety or ease, with the traction forceps, yet comparatively few of the latter are in use in general practise.

If a rupture of the cervix or peritoneum does occur, repair the latter from at once to within twenty-four hours, and the former within forty-eight hours, according to the condition of the patient. In repair, the important thing to remember is that the tear is from within outward; that in early repair the parts will come as naturally into adaptation as a tear in any other part of the body. If the attendant is not competent to do this, then justice to both himself and patient demands that he should at once call in some one who is. It is a shame to allow one who trusts her welfare into the hands of another to be left to drag out the life of an invalid, through the neglect of the one so trusted.

With many young physicians, and some not young, there is a false idea that to call in another more competent man is a sort of "give away;" that the patient or family will regard it only as a want of skill on the part of the attendant if he does so. It is a great mistake. That young doctor who has the good sense to call in experience in a difficult case will win nine times in ten over the "know it all," and keep the confidence of his patient besides.

When version is necessary, the rule in general practise is to proceed by the podalic method. The combined method of internal and external manipulations is preferable. There are comparatively few general practitioners who are competent to perform version by the external method only. This last method has an element of uncertainty about it that bars it from common usage. The same rule as to dilated or dilatable os is to be followed in version as in the use of forceps; otherwise the same unfortunate results follow. Whatever question may arise as to the advisability of administering ergot in any stage

of labor, when version is necessary its use is to be very much deplored. Cases have come to the knowledge of the writer in which its administration has caused hours of delay from strong contraction in spite of anesthesia. Gentleness and slowness save the parts, as well as the reputation of the attendant. In post-partum hemorrhage, one serious danger is in the practitioner not having at hand the necessary means to deal with the condition. Ergot is generally the only thing in the bag for that purpose. A good big dose is given by the mouth, and the patient is nearly pulseless before it can have any effect. No practitioner should go to an obstetric case without having with him prompt, effective means to meet emergencies. Yet this is not commonly done. Ergot and a hypodermic syringe satisfies the consciences of too many. Once the writer was so careless that not even these were at hand when a gush of blood flowed out that covered the arm to the elbow. It was winter, and, fortunately, close by the bed was a window, the sill piled with snow. To open it, make a snowball, and push it into the uterus, was the work of a minute. That snow saved the patient's life, and the event taught the attendant a lesson he never forgot.

It is not necessary to weary you with the many things that may be done in these cases. The point I wish to make is that the means are to be at hand, not in the office or drug store. There are cases, not very common, in which, after labor is completed, the patient clean and comfortable, with a well contracted uterus, hemorrhage occurs one or more hours afterwards. The attendant, hastily recalled, finds the uterus large and contracted on a solid clot, and the hemorrhage stopped. It is wisdom to let that clot alone. Usually it is expelled in a short time, and in the process the uterus contracts naturally.

After completion of labor, perseverant insistence on cleanliness is to be the rule *without exception*. That, and many other commonplaces, might be taken up, both as to mother and child, but enough has been mentioned to serve the purposes of this paper. Our journals are full of the details of great things; our literature is approaching completeness in theory and practise of the uncommon. Many a practitioner who longs for an opportunity to distinguish himself by an operation never takes time to ascertain if his obstetric patient uses a clean syringe. The careful "family doctor" frequently hears from a new patient, "Doctor, this was not done in any of my previous confinements.

Is it necessary?" Not infrequently the consultant physician finds that nearly all the preventable aids have not been used, and this not from ignorance but neglect.

This paper is not the vaporings of a "scold." The experiences of nearly thirty years emphasize the necessity of careful attention to the common, as well as the importance of readiness to meet the uncommon. None know better than the writer how simple this paper appears to many. None know better than he who addresses you how very commonplace it is. It is so intended. But, gentlemen, the careful, conscientious attention to the commonplaces means comfort, health, happiness, perchance the very existence, of her to whom every man who is a man bows in respectful reverence; of her whom every one of us is bound to protect, care for, and save, if the need be, even at the peril of his own life—the American Mother.

---

#### THE STATISTICS OF THE SERUM TREATMENT OF DIPHTHERIA.

PHOTIADES (*Archives Générales de Médecine*, January, 1898) shows that recently endless confusion has arisen in the study of diphtheria. In place of Troussseau's clinical classification of sore throats into true diphtheritic angina as opposed to toxic, infective and malignant angina, the presence of Loeffler's bacillus is now sufficient to fix the diagnosis of diphtheria. To adapt the new facts of bacteriology to one's clinical knowledge becomes more and more difficult. For instance, Gougenheim finds diphtheria to be much more common in adults than is usually supposed; besides, in its membranous form it occurs commonly as lacunar tonsillitis. He says every acute case of sore throat should be examined bacteriologically for fear of missing diphtheria. A harmless catarrhal angina may reveal Loeffler's bacillus (Gahli and Deucher). There are typical and atypical Loeffler's bacilli; typical but not virulent pseudo-diphtheritic bacilli (Park). Virulent Loeffler's bacilli may cause a local non-contagious disease, fibrinous rhinitis (Scheinmann). The pseudo-membrane, formerly the clinical and pathological criterion of diphtheria, is not a product of a specific bacillus, but may be produced by streptococci, staphylococci, or the bacterium coli. The bacillus diphtheriæ is hardly ever present alone (Danelo and Ruault). Severe septic diphtheria is not caused necessarily by an

associated infection, for in some cases streptococci cannot be found in the internal organs, and when they are the symptoms during life may not have pointed to septic diphtheria at all (Kuttner and others).

After all this it is not surprising that statistics have been made to prove (1) that the serum treatment has almost suppressed mortality, and (2) that since this treatment was begun the mortality is as high as ever. Thus, without considering the conflicting statistics of individuals, it has been shown that the serum has increased the mortality at Trieste, St. Petersburg, and Moscow; has diminished it enormously at Paris, Berlin, Vienna, and Budapest; and has had no influence on it at Leipzig, Milan, and London. In America, Coakney has shown for Boston, New York, and Brooklyn: (1) that the declared cases of diphtheria have increased enormously; (2) that though the relative mortality (percentage of declared cases) has diminished since the serum treatment, the absolute mortality calculated on the total population is as high as in the worst years since 1882. Though the public demand that every clinician should have an opinion as to the value of serum, either for or against, statistics are perfectly useless up to now in helping him to form one. He must therefore fall back on his own resources, which are those of clinical empiricism. It is enough for him that the serum acts, and that chance has been excluded from the cases where it succeeds—that is, he must consider the individual, not masses of statistics. No one who has seen the membrane clear up, the natural voice return if the nares are involved, and convalescence begin within forty-eight hours in a case which experience shows to be very severe, can doubt the good done by the serum. Its failure in certain cases is no reason for doubting its use. Everything points to the fact that diphtheria toxins vary greatly in virulence, and it is possible that bacteriology may prove eventually that some diseases, considered absolutely specific, are not so. For this, theories of bacterial symbiosis have prepared us, and Windrath has shown that there is nothing specific in the toxins of specific bacteria. It accords with this, that the author has often used the serum in cases which were clinically severe diphtheria, but where bacteriology showed streptococci to be in the majority, with as much success as in those caused by Loeffler's bacillus alone.—*British Medical Journal*, Feb. 12, 1898.

### THE TREATMENT OF INFANTILE DIARRHEA.

With the advent of the hot season physicians will once more meet with a large number of cases of more or less severe diarrhea affecting young children, and in many instances will come face to face with such grave symptoms that the malady will become in their eyes one of the most serious which they have to treat. Further than this, the mortality from the diarrheal affections classed under the head of cholera infantum is so large that we must all take great interest in any measures which look towards the diminution of its severity. During the past year a valuable practical paper was published by Langford Symes in the *Dublin Journal of the Medical Sciences*. He divides the diarrheas of children into those which are dyspeptic and those which are infective. These dyspeptic diarrheas usually arise from the digestion of foods unsuited to the digestive apparatus of young children, or their use in quantities over and above that which the stomach and intestines can utilize. The infective diarrheas, on the other hand, are

produced by the ingestion of milk or other articles of food which have undergone decomposition changes or which contain infectious micro-organisms. In either case the chief symptoms, as is so well known, consist of restlessness, abdominal pain, frequent grassy-green and watery stools containing now and again small amounts of mucus and possessing a peculiarly foul-smelling or mousy odor, which is peculiarly characteristic. If the diarrhea persists, the child, even in a very short time, suffers from thirst, a pinched face, and pursed expression about the mouth, with sunken eyes and cold skin. Sometimes, too, there may be nervous symptoms manifested in twitching of the hands and associated with depression of the fontanel.

Where the cases are more prolonged prior to the development of serious general nervous symptoms, the patient loses weight and is sometimes thought to have consumption of the bowels. The stools are particularly offensive, and in nearly all cases contain undigested coagula of casein. Quite frequently, because of the constant tenesmus and straining, prolapse of the rectum takes place. Finally, that state which has been called spurious hydrocephalus, a condition of depression of the fontanel, pinching of the face, and cool skin, apathetic eye, and lastly coma, is developed. These conditions can be avoided in a certain proportion of cases by the use of pure milk or by sterilizing it, by the maintenance of proper ventilation, and by removing the child from the exposure and great heat. But in a certain proportion of cases even these protective influences seem to fail, and where the infection is severe the symptoms come on with such appalling severity and rapidity that they necessarily create great alarm. Under these circumstances the chief danger which threatens the patient is collapse, and the treatment is therefore directed towards its prevention, towards support of the system, and for the purpose of removing the cause of the attack. Symes thinks that the general management should consist in rest, washing the mouth with glycerin or borax or diluted peroxide of hydrogen in the strength of two per cent., removing irritating particles of decomposing food from the bowels by a dose of castor oil, amounting to a drachm for a child of a year, or half a drachm for a younger child. He suggests the following prescription in attacks which are somewhat subacute or chronic and where there is no great need of hurry in unloading the bowels:

- ℞ Olei ricini, 5 minims;  
Mucilaginis acaciæ, 15 minims;  
Aque menthæ piperitæ, 1 drachm.

This to be given every hour until the bowels are moved. He also directs that one of the most important factors in the case is to change the milk at once, except in the case of infants who are at the breast, who should be allowed no other food or drink save the breast milk. In other infants only milk diluted one-half should be given, this dilution being made of pure water or by the use of barley water. In children who are old enough to take soda water, the bubbles of gas will prevent the formation of tough curds. Peptonized milk may be employed, or even condensed milk may be used. In some cases, particularly where there is reason to suspect the milk supply, sterilized milk should be employed or milk that has been Pasteurized, but it must be remembered that Pasteurization does not render innocuous milk which is derived from tuberculous animals. Careful attention should also be paid to the feeding-bottle, which should have no tube, the nipple and the glass being kept scrupulously clean. All starchy foods should be eliminated from the diet, and it may be well in some cases to give small doses of calomel. In other instances after the bowels have been thoroughly moved the salicylate of bismuth may be used. Sometimes minute doses of Dover's powder may be added to it.

We have already called attention in previous years in the editorial columns of the *THERAPEUTIC GAZETTE* to the great usefulness of intestinal irrigation in many of these cases. The irrigation may extend high up into the bowel and be performed with the aid of a soft-rubber catheter and a tube running from the ordinary fountain syringe. The fluid used had better be normal salt solution. Washing out the stomach has been recommended by some physicians, but as a matter of fact lavage in children is exceedingly difficult to perform.

The question as to how much we shall administer sedatives is a grave one. Personally, we have rarely, if ever, seen a case in which it seemed to us that nervous sedatives were indicated. Symes, however, suggests the use of the following prescription for a child of three months:

- ℞ Tincturæ opii camphoratæ, 1 minim;  
Glycerini acidi carbolicæ, 2 minims;  
Olei ricini, 5 minims;  
Mucilaginis acaciæ, 15 minims;  
Aque menthæ piperitæ, enough to make 1 drachm.

This is to be given every few hours.

As restoratives for threatened collapse we should give the child abundance of pure fresh air, brandy or strong coffee if needed, and sometimes from one-fourth to one-half grain of camphor suspended in mucilage with glycerin and used as a general diffusible stimulant. Should evidences of great exhaustion and feebleness be apparent as the result of profuse purging, which has resulted in depriving the tissues of fluid, hypodermoclysis with normal saline solution is to be performed.

#### UNTOWARD EFFECTS OF CHLOROFORM RARELY RECOGNIZED.

Notwithstanding the fact that chloroform has been administered so many thousand times throughout the civilized world during a period covering many years, the profession is constantly learning additional facts in regard to its powers, and, as is well known, medical literature has teemed during the last decade with experimental and clinical reports concerning its physiological action, its practical advantages and dangers. Those that have been most interested in the drug have also recognized that it is capable of undergoing decomposition both when in its fluid and vaporous state, and that in both of these conditions the results of the decomposition are capable of producing serious symptoms in a patient and even in those who surround him during the operation.

We have been surprised to find how few surgeons and physicians are acquainted with the fact that chloroform vapor is decomposed in the presence of the ordinary gas flame and that irritant fumes are thereby set free in the air of the room which are capable of seriously inflaming the air-passages of both operator and patient, although as a rule it would seem that the patient fares better than those who are carrying out the operative procedure.

These irritant vapors that we have spoken of consist principally of hydrochloric acid and chlorine, and both of these are known, of course, to be powerful inflammatory agents. In this connection two reports which have recently been made to the London *Lancet* are of interest. One of these is made by the Berlin correspondent, who writes of such an accident having occurred at the Catholic Hospital at Herne, Westphalia; and Dr. Waddellow writes to *The Lancet* of May 12 of a case in which chloroform was administered in a small room poorly ventilated, which was

warmed by an oil-stove and illuminated by a lamp and candle. During operation about half an ounce of chloroform was spilled when an attempt was made to refill the drop-bottle, and almost immediately a pungent, disagreeable smell was noticed, which speedily attacked the whole respiratory tract of the attendant physicians to such an extent that the operator was almost overpowered by it and the nurse was seized with a violent attack of coughing. Dr. Waddellow felt the results of the irritation of his bronchial mucous membrane for a period of four days, and this notwithstanding the fact that the purest chloroform obtainable, possessing no odor of any free chlorine, had been employed.

The results at the Herne Catholic Hospital were far more serious than this. The writer of this editorial was taught a similar lesson some years ago when using chloroform in a room with a very low ceiling, which had a gas-jet close to the chloroform inhaler. So intense was the irritation of the respiratory passages produced by the fumes of the chlorine under these circumstances that a suffocative spasm of the larynx occurred, requiring that fresh air be obtained at once, and this was followed by a severe laryngitis which lasted for a period of nearly two weeks and was accompanied by a mild ulcerative process. It is important to remember, therefore, that chloroform is under certain circumstances far more capable of producing serious respiratory difficulty than is ether, and in every instance where it is possible electric light should be utilized when this drug is used for anesthetic purposes. Where this light is not obtainable the lamp or gas-jet should be so arranged as to be far removed from the inhaler and the light be concentrated upon the wound by means of a reflector.

---

#### THE TREATMENT OF GASTRIC ULCER BY LARGE DOSES OF BISMUTH.

---

Gastric ulcer has been treated by very many methods, some of which radically differ from one another, and the use of bismuth in this affection is by no means recent. Within the last few years, however, it has been suggested by Fleiner that good results follow the use of massive doses of this substance. This clinician employed as much as 300 to 450 grains of bismuth in suspension in water, poured into the stomach by means of a stomach tube after previous lavage, and in his paper he referred to the experi-

ments of Mattheys upon the action of bismuth in hastening the cure of experimentally produced ulcers in the stomachs of dogs.

At a recent meeting of the Manchester Therapeutical Society, Dreschfeld read a paper upon this subject in which he protested against the use of the stomach tube as a method of administering these large doses of bismuth, on the ground that it is not wise to pass a tube into an ulcerated stomach. He stated that he had employed from thirty to fifty grains of bismuth subnitrate three times a day, suspended in water and swallowed without the aid of a tube. Under these circumstances he found the condition rapidly relieved, vomiting ceased, and digestion improved, although he allowed light nitrogenous food, such as fish or fowl, to be given. Ultimately the ulcer healed. These large doses of bismuth have never in his experience produced constipation, but rather a slight tendency to pain and diarrhea. Dreschfeld has also found this method useful in both acute and chronic cases and also in acid dyspepsia with neurasthenic condition.

The writer of this editorial has also employed these large doses of bismuth since reading Fleiner's paper with considerable success, and regards the method as being so valuable as to be worthy of trial in all cases in which this obstinate affection presents itself for treatment. It will be interesting to notice whether any evidences of chronic bismuth poisoning, such as have been produced from the external application of large quantities of bismuth, will be recorded.

---

#### WHAT OPERATION CAN DO FOR CANCER OF THE TONGUE.

---

The results following operative interference in cases of cancer of the tongue have been so uniformly unsuccessful that certainly the medical practitioner, and often the surgeon, is loath to advise active intervention. In the slight lesions, for the removal of which a partial operation is undertaken, the disease returns either *in loco* or in the neighboring lymphatic glands. When the tongue is thoroughly infiltrated its total removal is required. It is commonly accepted that this operation has to its discredit a large immediate mortality, and even though the patient recover from operation that the disease will certainly recur. A study of hospital statistics

in general and the summarizing of individual experience, which in this country is certainly limited, would justify the gloomy prognosis just outlined and would seem to indicate that conservatism might offer the patient a longer life than would intervention.

A contribution by Butlin based on a personal experience of 102 patients, all of whom except seven he has been able to trace, gives ground for the belief that the prognosis of tongue cancer is not more serious than that of this affection in other regions of the body, and offers further encouragement to the surgeon to operate at as early a period as possible and to make his operation rationally extensive.

Of Butlin's hospital cases there were sixteen per cent. of cures—*i.e.*, that percentage well more than three years after operation. Of the private cases twenty-six per cent. were cured. Moreover, the mortality of operation in the private cases was about one-ninth that of the mortality of the hospital cases.

The reason for much better results in private practise is based upon the fact that such cases always come earlier for operation.

Of the cured cases, it is to be noted that the disease in the large majority of them is situated in the anterior two-thirds of the tongue. There is evidence, however, to show that even when it is situated far back of the dorsum, or along the border in the neighborhood of the anterior half arches of the fauces, it may be treated with success, provided it has not invaded the tonsillar and neighboring regions. Among the private cured cases there was not one in which the glands were removed at the time of operation on the tongue or afterwards, thus showing that all of the successful cases were taken early. Among seven cured hospital cases five had the glands removed at or after operation, and in four of these they were proved by microscopic examination to be cancerous.

In the complete group of 102 cases the entire tongue was only removed sixteen times, and an analysis of these sixteen cases shows that four of the patients died of the operation and two of them shortly after their return home; that five suffered from recurrence *in situ*; and only one was cured.

The question of the removal of the entire tongue is one of considerable importance. The operation is a dangerous one; the patient is crippled not only in regard to speech, but in regard to taking solid food, and there is proof that a removal of a portion of the tongue is sufficient to cure a considerable

percentage of patients and to save a much larger percentage of patients from a recurrence of disease within the mouth.

Butlin states that he always aims to remove the cancer with three-quarters of an inch of apparently healthy tissue around it in every direction. When, however, the disease is on the border of the tongue, his routine practise is to remove one-half the tongue for an inch behind the margin of the disease.

Butlin's tables show in all thirty cases free from recurrence; six from one to two years, four from two to three years, and twenty for more than three years. Some of these have remained well for upwards of twelve years. He states that a comparison of these results with those which he was able to furnish ten or eleven years ago is so satisfactory that they lead to a more hopeful view of the operative treatment of cancer of the tongue than formerly. At that time the statistics collected by Barker afforded only five per cent. of cures on the three years' limit, in a table of 170 patients. Butlin holds it is fair to say that the prognosis of cancer of the tongue, when the disease is situated in the anterior two-thirds, whether in the substance or on the border of the organ, is not by any means bad, when compared with the prognosis of cancer of most other parts of the body.

Butlin points out that lymphatic involvement is the most serious and unmanageable complication with which the surgeon has to deal. The disease, though malignant, is locally malignant, for it is so constantly limited to the tongue and the neighboring lymphatic glands of the neck that the prospect of dissemination may be dismissed. About seventy per cent. of the cases can be so successfully treated by operation that there is little fear of recurrence *in situ*, but of these seventy persons probably thirty will die—perhaps as many as forty—of affections of glands of the neck.

Von Winiwarter noted that in most cases glandular involvement occurred only after the disease had existed several months, but that exceptionally it occurred within a few weeks of the primary outbreak of the disease, and in a certain few cases the cancer of the mouth and the glandular disease were discovered at the same time. There is no means of discovering which cases of cancer of the tongue are likely to be associated with secondary cancer of the glands, unless there is enlargement of the glands at the time of operation on the tongue. Nor can we foretell how soon the removal of the cancer of

the tongue will be followed by secondary affection of the glands of the neck. Hence it is wise to regard every patient with cancer of the tongue as having the glands of the neck already inoculated.

The procedures which are naturally suggested by this conception are to clear out the glands anatomically connected with the affected portion of the tongue or to wait until they are slightly enlarged, hence probably diseased, before performing this operation.

The expectant method, though plausible, is open to many and obvious objections. As to the advisability of cleaning out the chain of glands in anatomical relation to the affected part of the tongue, the greatest uncertainty exists as to the group of glands which is likely to be affected in any individual case of cancer. Sometimes the affected glands are behind the angle of the jaw; sometimes they are in the floor of the mouth, behind the symphysis of the lower jaw; sometimes they are half-way down the neck on a level with the thyroid cartilage. In spite of this uncertainty Butlin finds that a study of anatomical plates, together with a careful consideration of the clinical course of cancer, shows that the lymphatics of the tongue are so disposed that infection passed through one or more of four groups of glands: (1) the submental group, which lies beneath the floor of the mouth behind the lower jaw; (2) the submaxillary, some of which actually lie in the substance of the salivary gland; (3) the parotid, and (4) the carotid, which lie over the course of the carotid artery and particularly over the bifurcation of the common carotid. As a rule all the lymphatics of the anterior half of the tongue, whether from the dorsum, the border, or the under aspect, pass through one or more of the three anterior groups of glands. Hence in the majority of cancers of the tongue, especially those that can be removed so that they are not likely to occur *in loco*, it may be foretold that they will inoculate one or more of the three anterior groups of glands, particularly the submaxillary and carotid groups. The removal of these three groups would then offer a reasonable prospect of preserving the patient, in any given case, from glandular affection. If in addition the parotid glands, or those of them most likely to be affected, could be removed during the same operation, an increased prospect of success would be afforded, since it cannot be doubted that occasionally lymph from the

anterior portion of the tongue does pass directly or indirectly through this group.

Butlin states that bearing these considerations in mind he has devised and carried out an operation which removes all the contents of the great anterior triangle of the neck, including the submaxillary salivary gland. The anterior triangle is thoroughly exposed by an incision about seven inches long on the anterior border of the sterno-mastoid muscle from the mastoid process to below the thyroid cartilage, and a second incision from the symphysis of the lower jaw to the first incision about the upper level of the thyroid cartilage, and raising up the two triangular flaps which are thus mapped out. The dissection is commenced from the apex of the triangle below, and carried upwards. The large vessels are exposed for a considerable distance, and finally the submaxillary salivary gland is taken out. A very careful dissection is made of the triangle so that the connective tissue and glands are all taken out in one continuous mass. Search is made between the muscles in front for one or two deeper-seated lymphatics, and the glands in front of the parotid gland and about the angle of the jaws are removed with the other contents of the triangle. The submental and parotid glands are not so easily and certainly removed in this operation as the submaxillary and carotid groups. The dissection occupies from an hour to an hour and a quarter. Experience has taught Butlin that disease of the tongue should be first removed, and when the patient has had time to recover from this operation, and can take food well, the removal of the contents of the anterior triangle may be undertaken without fear.

Butlin's results, based on a singularly extended experience, are certainly most encouraging. They are not dependent upon the thorough dissection of the lymphatic system of the neck, since he has practised this procedure only within the last eighteen months, nor are they based upon more radical or extensive operations than those commonly performed by surgeons. They seem to prove that the gloomy prognosis of cancer of the tongue is dependent in the main on the unfortunate results of hospital experience, and they accentuate the importance of urging upon medical men and upon the laity the need of early surgical attention to every lesion of the tongue, no matter how apparently trivial, which does not yield quickly or kindly to ordinary cleansing treatment.

## Reports on Therapeutic Progress

### *THE INFLUENCE OF BORAX AND BORIC ACID UPON NUTRITION, WITH SPECIAL REFERENCE TO PROTEID METABOLISM.*

In the first number of the *American Journal of Physiology* for January, 1898, CHITTENDEN and GIES tell us that moderate doses of borax up to five grammes per day, even when continued for some time, are without influence upon proteid metabolism. Neither do they exert any specific influence upon the general nutritional changes of the body. Under no circumstances, so far as they have been able to ascertain, does borax tend to increase body weight or to protect the proteid matter of the tissues.

Large doses of borax, five to ten grammes daily, have a direct stimulating effect upon proteid metabolism, as claimed by Gruber; such doses, especially if continued, lead to an increased excretion of nitrogen through the urine, also of sulphuric acid and phosphoric acid.

Boric acid, on the other hand, in doses up to three grammes per day, is practically without influence upon proteid metabolism and upon the general nutrition of the body.

Borax, when taken in large doses, tends to retard somewhat the assimilation of proteid and fatty foods, increasing noticeably the weight of the feces and their content of nitrogen and fat. With very large doses there is a tendency toward diarrhea and an increased secretion of mucus. Boric acid, on the contrary, in doses up to three grammes per day, is wholly without influence in these directions.

Borax causes a decrease in the volume of urine, changes the reaction of the fluid to alkaline, and raises the specific gravity, owing to the rapid elimination of the borax through this channel. Under no circumstances have the authors observed any diuretic action with either borax or boric acid. The latter agent has little effect on the volume of the urine.

Both borax and boric acid are quickly eliminated from the body through the urine, twenty-four to thirty-six hours being generally sufficient for their complete removal. Rarely are they found in the feces.

Neither borax nor boric acid have any influence upon the putrefactive processes of the intestine as measured by the amount of combined sulphuric acid in the urine, or by Jaffe's indoxyl test. Exceedingly large

doses of borax are inactive in this direction, not because the salt is without action upon micro-organisms, but because of its rapid absorption from the intestinal tract.

Borax and boric acid, when given in quantities equal to 1.5 to 2 per cent. of the daily food, are liable to produce nausea and vomiting.

Owing to the rapid elimination of both borax and boric acid, no marked cumulative action can result from their daily ingestion in moderate quantities.

At no time in these experiments was there any indication of abnormality in the urine; albumen and sugar were never present.

### *THE THERAPEUTICS OF VENESECTION.*

ALBERT ROBIN, of Paris, has contributed to the *Medical Press and Circular* of February 9, 1898, his views as to venesection and its value. He tells us that he has in all bled fourteen patients of late; ten of them were benefited thereby, four were not. The four cases of failures were: One case of cerebral hemorrhage, with ventricular distention; one case of acute nephritis, with respiratory uremia. The patient was bled twice in rapid succession, 250 grammes of blood being withdrawn each time. Post-mortem the lungs were found to be in a state of acute edema. The third patient was suffering from Bright's disease due to lead poisoning, complicated with epileptiform attacks and intense dyspnea. He suspected uremia, and withdrew 300 grammes of blood. The patient died the next day, and was found post-mortem to be affected with tuberculous meningitis. The last case was one of cardiac asystole, with cyanosis, in which digitalis had produced no effect. The patient was bled, but derived no benefit therefrom. Post-mortem a rupture of the spleen was found, the hemorrhagic focus being limited by adhesions.

The ten cases in which blood-letting proved beneficial were: One case of uremic coma which had lasted twenty-four hours, with left hemiplegia and conjugate deviation of the head and eyes to the right; 250 grammes of blood was withdrawn, and this was followed within thirty-six hours by disappearance of the cerebral phenomena. One case of dyspneic uremia with hydrothorax, in which bleeding was followed by increased flow of urine and diminution of the dyspnea; the immediate benefit was extremely marked, but the patient died a few days later. One case of uremia with hydrothorax, in which the

patient was bled *in extremis*; he lived three days after the operation. One case of asystole, due to aortic incompetence, with pulmonary congestion. The patient rapidly improved after withdrawal of 200 grammes of blood. One case of nephritis with renal congestion, relieved by the simple withdrawal of 150 grammes of blood. One case of arteriosclerosis with mitral lesions and Bright's disease. The patient improved after blood-letting; he then had a relapse, but once more improved when a further 100 grammes of blood was withdrawn. One case of chronic lead poisoning with mitral and aortic lesions, much enlarged heart, and cardiac cirrhosis. The patient developed attacks of uremia, which improved greatly under blood-letting. One case of uremia in which the patient, who was in a comatose condition when seen, recovered completely. One case of arteriosclerosis with nephritis following upon erysipelas, edema, anasarca, and very severe dyspnea. Digitalis only began to act after 150 grammes of blood had been withdrawn. Lastly, one case of asystole, with anasarca, in which the patient's condition began to improve after the emission of 200 grammes of blood.

The foregoing clinical results confirm those obtained by experiments. There is no doubt that blood-letting was at one time resorted to far too readily, but the practise did not deserve on this account to be so completely discarded from modern therapeutics as has been the case.

We must bear in mind, then, that blood-letting is distinctly indicated whenever it is necessary to stimulate the circulation of the blood, in cases of vascular stasis in mitral and asystolic patients, and in acute edema of the lungs. It may even be asserted that blood-letting, although not specifically indicated against any particular morbid state, constitutes, nevertheless, a valuable adjunct in a number of very dissimilar pathological conditions, provided they present the one element of defective nutrition, or to be more exact, of inadequate organic oxidation.

#### THE ACTION OF ATROPINE AND PILOCARPINE ON PERISTALSIS.

TRAVERSA (*Il Policlinico*, Nov. 15, 1897), being struck by the fact that injections of atropine caused constipation rather than increased emission of feces in horses, has investigated the action of this drug and also of pilocarpine. It was found that pilocarpine

accelerated and strengthened peristalsis, whilst atropine lessened and finally abolished the movements of the intestine. In each case the result is obtained through paralysis or stimulation of the ganglia and nerve endings in the intestine. From this it follows that belladonna is not likely to be of value in constipation from atony of the bowel muscle, but in the lead colic, where it is not improbable that the intestinal ganglia are irritated, belladonna may prove a useful remedy; and indeed in all cases when painful intestinal spasm, due to irritability of the intestinal ganglia, is present, the drug in question may be used with advantage.—*British Medical Journal*, Feb. 12, 1898.

#### THE USE OF MANGANESE IN THE TREATMENT OF DYSMENORRHEA.

Dr. O'DONOVAN writes in the *Medical News* of November 27, 1897, of his experiences with manganese in dysmenorrhea. He tells us that in the *Medical News* of April 6, 1889, he published an article, entitled "A Plea for the Use of the Manganese Compounds in Certain Forms of Dysmenorrhea," in which he drew the following conclusions:

1. The manganese compounds are valuable additions to the therapeutics of dysmenorrhea, and in a certain number of properly selected cases great benefit may be expected from their use.

2. Their use does not interfere in any manner whatever with the administration of iron or the vegetable tonics, but rather aids and is aided by them.

3. The best results from the employment of these remedies may not be obtained at once, and failure should not be confessed until after a continuous trial lasting three months.

4. So far as we know at present, the black oxide of manganese is the most convenient form for administration.

At that time the observations of Ringer and Murrell, of London, called attention to the benefit to be derived from the compounds of manganese in various menstrual disorders, and other clinicians had testified in their favor. Having enjoyed a certain vogue at the time, in the avalanche of new remedies which are being constantly exploited manganese seems to have lost its prominence, and is now seldom referred to. This is a mistake—a remedy, valuable in a number of cases, is being overlooked. That it is one which deserves to be rescued from oblivion and again presented for study and trial is

undoubted. The writer has been using manganese constantly since the appearance of the paper quoted, and is to-day as favorably impressed with it as when he reported his former observations. He holds it to be most valuable in the treatment of dysmenorrhea in unmarried women; and, until it has been faithfully tried during a period of not less than three months without intermission, he would use no other treatment.

Manganese will not relieve all cases; in some it produces no effect whatever, and in some few instances women have complained that their sufferings actually seemed to have been exaggerated; but when it does act favorably, it is such a boon that it cannot be overvalued. Unfortunately, one cannot foretell in a given case whether or not manganese will be of benefit; the writer has known it to fail when he had most reason to expect success, and to relieve when he feared it would fail, so that its use is somewhat empiric, and apt to lead to disappointment. This does not, however, change the fact that a large number of cases of dysmenorrhea may be relieved by its use in a way that no other drug can approach, and often after numerous others have been tried and discarded as useless. Even in these days of manipulative and operative gynecology there are many young women who would prefer to be treated by medicines rather than by instrumental interference; who are very naturally frightened out of the office of a physician who suggests a digital examination as soon as a history of dysmenorrhea has been elicited.

In the writer's hands the best effects from the use of manganese have resulted when the history is of general malaise before the flow begins, with some pain, growing rapidly worse as the flow is about to commence, and pain more or less severe during the first day. A good color or a pale face seems to have no bearing upon the action of the drug; its action appears to be upon the nerve centers concerned in the menstrual function, rather than upon the blood. It is no unusual thing to find a habit of dysmenorrhea which had existed for years yield at once to the exhibition of manganese.

One word about the administration of the drug. Some women experience considerable difficulty in taking it because of a very delicate stomach, which rebels against it. For this reason it is well to begin with a small dose, say one grain at a time, and gradually increase it. The writer has given five grains

three times a day during several weeks without any ill effect, but experience has taught him that three-grain doses will do as much good as a larger quantity, and that failure with that much cannot be changed to success by increasing the dosage. Often it is unnecessary to give even this much, but it may be properly pushed to this limit in doubtful cases.

#### *ON THE TREATMENT OF THE HEART FAILURE OF ARTERIOSCLEROSIS.*

The *British Medical Journal* of December 11, 1897, contains a paper by C. R. MARSHALL upon this subject. He tells us that his present paper is merely an appendix to an investigation which the writer made some time ago on the antagonistic action of digitalis and the members of the nitrite group. The research was suggested by the increasing use of vaso-dilators with digitalis in practice and the knowledge that little was known of their effect when given in combination. This treatment was first introduced by Huchard, to counteract the vaso-constricting influence of digitalis, and of late years it has been advocated by Balfour, Whittaker, Sansom, LeFevre, Da Costa, Forchheimer, Dabney, and Husemann. It has not, however, received universal approval (see Grainger Stewart), and further information on the point seemed necessary.

The cases of heart failure in which vaso-dilators combined with digitalis are recommended are those in which this condition is associated with thick-walled arteries. Here the peripheral resistance is increased, and it is obviously undesirable to augment it. Digitalis, although it braces up the heart, also contracts the blood-vessels, and in this way sets up a barrier to its cardio-tonic effect. When the vascular tone is lost this contracting influence is beneficial, but in the aged this is rarely the case. "The old bear digitalis badly," and the writer believes this is due to the fact that their arteries are thickened and less elastic.

As far as the heart failure is concerned, it is immaterial whether the arterial changes are the result of age or disease. In both cases the course of affairs, if the disease is allowed to continue, is the same. The simplest case is the physiological one, if such it may be called. From birth to death the structure of the arteries seems to be gradually changing. With the approach of old age the arterial walls become thicker and their elasticity diminishes; the peripheral resistance is increased and the heart hyper-

trophies. But sooner or later the arterial blood-pressure reaches its maximum, the heart begins to fail, and unless treated rapidly runs a downward course. The disease called the "senile heart" (Balfour) has developed. In arteriosclerosis a similar evolution occurs; heart failure sooner or later appears and the vascular becomes a heart affection. As pointed out by Huber, the condition of the small vessels of the heart is an important factor in the production of this heart failure. These vessels undergo the same changes as arteries in other parts of the body, and as they serve for the nutrition of the heart their effect is greater. Under the term "cardio-pathies arterielles" Huchard has described several clinical types of this disease, but these are perhaps best considered as part of the general affection.

From a therapeutic point of view the condition may be divided into three stages:

1. Early stage: thickened arteries with slight enlargement (hypertrophy) of the heart; increased intra-arterial blood-pressure.
2. Later stage: arteries somewhat thicker; marked cardiac hypertrophy; high arterial blood-pressure.
3. Last stage: arteries unchanged or somewhat dilated, but heart failing; marked cardiac dilatation; gradually sinking blood-pressure.

The last two stages Huchard denotes as "cardio-arterielle" and "mitro-arterielle" respectively. The first stage he calls "arterielle" (pre-arterielle, Ferreira), although he believes the primary change is in the heart and not in the vessels; and to a certain extent this view seems to be supported by an experiment of Thoma. Balfour, however, says "there is a consensus of opinion that the arterial system . . . is that upon which the finger of decay is earliest laid," and it is the author's own experience. From a therapeutic point of view, however, the origin of the condition is not of great importance; when treatment is required the arteries are always changed.

With the first and second divisions of this table we are not concerned. The symptoms are legion, and as regards treatment probably nothing is so useful as the iodides with an occasional mercurial or saline purge; vaso-dilators are advocated by some, but this treatment has not met with general approval. When, however, symptoms of heart failure set in depletive measures should be avoided and digitalis or some other cardiac tonic given. The question of the vessel-contracting

influence of digitalis now becomes of importance. Is it injurious? In some cases the author thinks not. Even in the heart failure of old age, or approaching old age, we sometimes find the pulse of low tension, although the arteries have thick walls, and in such cases digitalis alone, at least in the earlier stages, is by no means harmful. In the majority of cases, however, the arterial factor is an important one, and as far as possible should be relieved. But can vaso-dilators do this? In other words, are nitrites or the members of the nitrite group antagonistic in this respect to digitalis? Experimental observations lead us to conclude that they are, but not absolutely so. The two groups of substances, in fact, seem to be mutually antagonistic. As far as the effect on the blood-pressure of animals is concerned, digitalis diminishes the effect of nitroglycerin, and in part nitroglycerin counteracts the effect of digitalis. A similar action is obtained in man, but on account of the smaller dosage digitalis exerts less influence on the action of vaso-dilators. The commencement of action of these is delayed, the degree of action is somewhat less marked, and in some cases the duration of action is slightly curtailed. But even in advanced cases of heart disease which have been treated with digitalis for some time, sodium nitrite and its allies will act, although the effect is often comparatively slight. Nitroglycerin is least affected, the solid organic nitrates (erythrol tetranitrate, mannitol hexanitrate) most. As regards nitroglycerin, the delay in its action is rarely more than one minute, and the extent of reduction is but slightly modified; the principal change seems to be a curtailing of its effect. The indications for treatment are clear. For therapeutic purposes vaso-dilators are antagonistic to digitalis, but they seem to require more frequent administration than under normal conditions. The powerful physiological action of nitroglycerin and the comparatively large toxic dose enable us to push it to a considerable extent. But generally this is unnecessary, as digitalis is only given to produce a mild tonic effect. By carefully regulating the dose of this drug the writer believes that the use of vaso-dilators can to a large extent be avoided, but in such cases the dose must of necessity be small. The depressing effect of the vaso-dilators on the heart is of no therapeutic significance in this connection. It is true that experimentally, in large doses, nitroglycerin will antagonize the cardio-tonic effect of digitalis, but in medicinal doses the

depressant action of nitroglycerin is comparatively insignificant, and may be neglected.

The conditions in which the combined use of digitalis and vaso-dilators are indicated are numerous. Just as the only, or almost the only, indication for the use of digitalis is a failing heart, so the only indication for the use of vaso-dilators is a more or less incompressible pulse. Wherever the two are combined—that is, whenever a comparatively high tension pulse exists with heart failure—the combination will be of use. These conditions need not be specified. Marshall refers to angina pectoris. According to one eminent authority, anginal attacks most usually occur when arteriosclerosis is combined with coronary atheroma. It is generally acknowledged that cardiac pain is often accompanied by contraction of the arterioles; but this is not invariably the case, otherwise vaso-dilators would always prove of service, which they do not. In the majority of cases, however, an increased peripheral resistance exists, and sooner or later this reacts markedly on the heart and more rapid weakening follows. The anginal attacks now often subside and symptoms of heart failure develop; as has been said, the anginal case becomes a cardiac one. The administration of digitalis in these has not proved of unmixed benefit. It has toned up the heart, but it has contracted the vessels and the anginal attacks have again developed. To obviate this combination with a vaso-dilator has been tried, and apparently with success.

As regards dose and administration a few words are necessary. It is the universal custom to administer the combined drugs in mixture. This Marshall believes is a mistake. Digitalis acts upon the tissues very slowly. The most soluble preparation—digitalinum verum (Pharmacopœia Germ.)—will not produce an effect on the pulse under four to six hours, and with other preparations the delay is much longer. Sometimes it does not become evident for days. The vaso-dilators, on the other hand, act rapidly; nitroglycerin affects the pulse within two minutes; within three hours its effects have usually passed away; sodium nitrite acts within five minutes and lasts the same length of time; erythrol tetranitrate, in the solid form, commences in twenty to thirty minutes and continues seven to eight hours. From the mixture, therefore, we shall get nothing at first but the effect of the vaso-dilator; later we shall probably be giving an excess of digitalis. Owing to the slow assimilation

and retention of digitalis in the system we get practically a constant effect, at least for short periods, but this is not the case with the vascular drugs, especially where these are given infrequently. To keep down the tension of the pulse nitroglycerin and sodium nitrite should be given at least every three hours, and erythrol tetranitrate every six. Given less frequently the patient is periodically subjected to periods of high arterial tension of varying duration, which is what we wish to avoid. As in many cases it is sufficient to give digitalis once a day after it has commenced to act, it would seem advisable to give the two substances separately—the vaso-dilator frequently, the digitalis less frequently. The author suggests as a type of combination the administration of erythrol tetranitrate every six hours and one of the French granules of digitalin every one, two or three days, according to the progress of the disease and the effects of previous treatment. If a greater vascular effect was desired nitroglycerin frequently would probably be most beneficial. Other combinations might be used, but it is essential that the drugs should be used rationally and with a knowledge of their pharmacological action.

The combination of digitalis and spiritus ætheris nitrosi in mixture form seems highly reprehensible. The active vaso-dilator of this substance is ethyl nitrite, a gas insoluble in water; consequently it rapidly disperses when made into a mixture, and in a comparatively few hours has almost totally disappeared. If given at all sweet spirits of nitre should only be mixed with water at the time of administration.

---

*A FURTHER STUDY OF THE INFLUENCE  
OF ALCOHOL AND ALCOHOLIC DRINKS  
UPON DIGESTION, WITH SPECIAL  
REFERENCE TO SECRETION.*

An exhaustive research on this interesting topic, carried out by CHITTENDEN, MENDEL, and JACKSON, and published in the *American Journal of Physiology* for March, 1898, is of sufficient practical value to require attention. Some of the more important conclusions to be drawn from the results of the experiments which they have reported may be advantageously summarized here.

Upon the secretion of saliva, the presence of strong alcohol, or an alcoholic beverage in the mouth, has a direct stimulating effect leading to a sudden increase in the flow of saliva. This acceleration of secretion, how-

ever, is of brief duration. The stimulating effect is manifested not only by an increase in the volume of the secretion, but also by an increase in both organic and inorganic constituents. The effect produced is in no sense peculiar to alcohol, but is common to many so-called stimulants, such as dilute acid (vinegar), ether vapor, etc. Indeed, the effect is precisely analogous to that induced by an increase in intensity of stimulation, when the salivary glands are electrically excited through their nerves.

As to the possibility of alcoholic fluids absorbed from the stomach giving rise to an indirect stimulation of salivary secretion, or exercising any appreciable influence upon the composition of the secretion, their results give a negative answer. Thus, alcoholic fluids introduced directly into the stomach (of dogs) by injection through the stomach wall, thus doing away with any local action in the mouth, produce no appreciable effect upon the rate of secretion, as induced by a constant external stimulus, of either submaxillary or sublingual saliva. Even doses of alcohol sufficient to produce prolonged narcosis when introduced in this way fail to check the flow of saliva. There is likewise no specific influence exerted on the composition of the secretion. Hence, so far as their results go, alcohol and alcoholic fluids are without any specific stimulation of secretion while in the mouth cavity.

Upon gastric secretion, alcohol and alcoholic fluids have a marked effect, increasing very greatly both the flow of gastric juice and also its content of acid and total solids. Further, this action is exerted not only by the presence of alcoholic fluids in the stomach, but also indirectly through the influence of alcohol absorbed from the intestines. Thus, ordinary ethyl alcohol introduced into the empty stomachs of dogs, with the duodenum ligated, shows a marked stimulating action upon gastric secretion—as compared with the action of water under like conditions—increasing not only the volume of gastric juice very greatly, but also its acidity, content of solid matter, etc. Moreover, alcohol absorbed from the intestine, the latter being entirely shut off from the stomach, may likewise cause stimulation of the gastric glands, with a marked increase in the rate of secretion, etc. Whiskey, brandy, sherry, claret, beer, and porter, all agree in producing stimulation of gastric secretion. Further, as already stated, the gastric juice secreted under alcoholic stimulation is

more acid, contains more solid matter and more combined hydrochloric acid than the ordinary secretion. It is likewise strongly proteolytic.

If these results are considered in connection with our previous observations upon the influence of alcohol and alcoholic drinks upon the purely chemical processes of gastric digestion, it is seen that side by side with the greater or lesser retardation of digestive proteolysis caused by alcoholic beverages there occurs an increased flow of gastric juice rich in acid and of unquestionable digestive power. The two effects may thus normally counterbalance each other, though it is evident that modifying conditions may readily retard or stimulate the processes in the stomach according to circumstances. Foremost among the latter is the rapid disappearance of alcohol from the alimentary canal.

Since any influence exerted by alcohol or alcoholic beverages upon the solvent or digestive power of the gastric juice in the stomach must depend upon the presence of alcohol in the stomach contents, it follows that the tendency toward rapid removal of the alcohol from the alimentary tract by absorption must necessarily diminish correspondingly the extent of the retardation of gastric digestion which the presence of alcohol in the stomach may occasion. Since, however, the stimulation of gastric secretion induced by alcohol is brought about not only by the direct action of alcohol in the stomach, but also by the indirect action of alcohol absorbed from the intestine, it follows that possible inhibition of the digestive action of the gastric juice would probably be of shorter duration than the stimulation of secretion, and that consequently in the body alcoholic fluids would hardly lead to any retardation of gastric digestion. This point has been very carefully and thoroughly tested by numerous experiments on healthy dogs with gastric fistulæ, using proteid test meals, with the result that, certainly in the stomachs of dogs, digestion is not retarded in any pronounced degree under the influence of alcohol or alcoholic fluids. Of hastened digestion, the results obtained give little or no suggestion, and we must therefore conclude that the two diverse factors above referred to more or less counterbalance each other, so that gastric digestion in the broadest sense of the term is not markedly varied under the influence of alcohol or alcoholic fluids. This conclusion, it may be mentioned, stands in perfect har-

mony with the results of the investigations of Zuntz and Magnus-Levy regarding the influence of alcohol (beer) on the digestibility and utilization of food in the body. These investigators found by a series of metabolic experiments on men with diets largely made up of milk and bread, and on individuals accustomed and unaccustomed to the use of alcoholic beverages, that the latter did not in any way diminish the utilization of the food by the body.

Especially worthy of note is the rapid disappearance of alcohol from the stomach and alimentary tract when alcoholic fluids are taken. As results show, the introduction of 200 cubic centimeters of thirty-seven-per-cent. alcohol into the stomach of a dog with the duodenum ligated at the pylorus may be followed by the nearly complete disappearance of the alcohol in three to three and a half hours by absorption through the stomach walls into the blood. With the outlet from the stomach into the intestine open, the rate of absorption of alcohol is greatly increased. We may well believe, as stated by Ogata, that when six to eight grammes of alcohol is taken into the stomach in the form of wine or beer, that eighty to ninety per cent. of the alcohol will disappear from the alimentary tract inside of half an hour. Indeed, the writers' experiments on dogs with gastric fistulæ lead to this conclusion. Thus, in one experiment fifty cubic centimeters of twenty-per-cent. alcohol was introduced into the stomach, and on withdrawing the stomach contents half an hour later no alcohol whatever was found in the forty cubic centimeters of fluid obtained. In view of this rapid disappearance of alcohol from the alimentary tract it is plain that alcoholic fluids cannot have much, if any, direct influence upon the secretion of either pancreatic or intestinal juice.

#### THE TREATMENT OF IDIOPATHIC ULCERS OF THE CORNEA IN CHILDREN.

Mr. JOHN GRIFFITH in *Treatment* of December 9, 1897, in speaking of vascular or strumous ulcers of the cornea, emphasizes the fact that the symptoms are invariably severe, that the poor sufferer avoids the light, and mopes away in a corner of the room with his head buried in a pillow or in his hands damped with tears. The lacrimation is profuse, the scalding tears spurting out from between the lids when an attempt is made to separate them. The nose also runs with

lacrimal secretion, in consequence of which we find eczema around the nasal orifices as well as the palpebral fissures. The blepharospasm is extreme, and a proper examination often demands a general anesthetic.

The poor parents are troubled at seeing their child, perhaps their only one, suffer in this manner, and it is difficult for them to carry out the treatment prescribed.

Here is a child, predisposed by heredity to low types of inflammation, and rendered weak through errors of diet, bad hygiene, or protracted convalescence after one of the exanthems, suffering from strumous keratitis. How are we to cure it? The cornea, being by nature an avascular structure, constitutes one of the earliest indicators of physical weakness; it is, in fact, a natural tissue-dynamometer.

The constitutional treatment recommended in the other forms of keratitis will hold good here; it will only be necessary to enter into the question of local treatment.

An ointment composed of atropine, cocaine, and yellow oxide of mercury, applied night and morning, with massage, is sufficient in most instances to effect a rapid cure.

℞ Hydrarg. oxid. flav., gr. x;  
Cocain. hydrochlor., gr. x;  
Atropinæ sulphat., gr. ij;  
Vaselin. puriss., ʒ j.

Fiat ung. Nocte manequa utend.

Should the eye be intolerant of the mercurial salt, it must be left out till the symptoms are subsiding. If the ointment still irritates, the following drops should first be applied:

℞ Acidi borici, gr. xv;  
Cocain. hydrochlor., gr. x;  
Atropin. sulphat., gr. ij;  
Aque destillat., ad ʒ j.

Ft. guttæ. Ter die utend.

Should the lacrimation still be profuse and dermatitis ensue, the strength of the atropine should be increased, for it will arrest the secretion of tears—the source of the eczema—and exert then more fully its sedative action. The eczema must be treated with boric acid ointment.

If after a fortnight or three weeks' treatment the symptoms do not subside, one of two methods may be adopted—either anesthetize the child and cauterize the ulcers, or better still, paint the outside of eyelids with some pure nitrate of silver stick. It is a plan recommended by Argyll-Robertson, and the rapidity with which the symptoms subside is simply marvelous. Another plan of treating chronic ulcers is to evert the eyelids and

paint the conjunctiva with a solution of nitrate of silver (gr. x, ad ʒ j), even if they are not secondary to conjunctivitis. This procedure Griffith has found serviceable, though it should only be adopted when the ulcers are of long standing.

A few remarks as to the general care of the child. Daily outdoor exercise is very necessary; tinted goggles are far preferable to bandages or shades; and during the daytime the child should never be allowed to be in darkness—merely a dim, religious light—for otherwise the photophobia will become exaggerated, and the resulting blepharospasm will originate a chronic state of affairs which we wish to avoid. Stooping the head is bad and encouraged by the use of broad shades, but obviated by tinted goggles.

In conclusion, Griffith mentions the likelihood of corneal perforation and prolapse of iris. If Descemet's membrane is seen protruding as a vesicle, a timely paracentesis of the anterior chamber will anticipate Nature and be less harmful. If an anterior synechia has been acquired, an iridectomy at a later date may be required.

---

#### A REVIEW OF THE LITERATURE OF KOCH'S TUBERCULIN "R."

J. DUTTON STEELE sums up the facts in regard to this bacterial product in the *International Magazine* for December, 1897, as follows:

The new preparation, if uncontaminated, does not seem to be more harmful than the old tuberculin if very carefully given. The dosage suggested by Koch is probably too severe. Much is left to be desired in the preparation of the material. In its present form it is usually contaminated. The greatest element of danger is the possibility of the presence of living tubercle bacilli. It may also contain streptococci, diplococci, staphylococci, and various saprophytic bacteria. Certain outputs of the substance are clearly stronger than others and more likely to cause serious reaction.

The injections are accompanied by much discomfort to the individual. The point of entrance of the needle usually becomes the seat of considerable inflammatory reaction and occasionally of abscess formation. Much of this may be accounted for by the contamination of the preparation or faulty asepsis in its administration; but even in the absence of the former and with extreme care in the latter, as in the series reported by Bussenius,

some infiltration may occur. Very marked systemic reaction occurred in some part of the course of injection, but there is a reasonable suspicion that this may be caused by the apparent variation in strength of the preparation. It is possible that, if this uncertainty is overcome, immunity against the products of the microbe may be reached without undue reaction.

The immediate effects of the preparation upon existing lesions of the lung, larynx and middle ear are too indefinite to admit of any certain opinion being formed concerning them. In lupus, in various suppurating tracts, and in one noticeable case of tuberculosis of the uterus and its appendages, the remedy seemed to be of value; but whether of greater worth than the old tuberculin can only be determined by longer observations.

Koch's experiments apparently established the fact that in them an immunity against both the bacteria and their products could be obtained, and inasmuch as several patients after completing the course of injections stipulated by Koch received large doses of the old tuberculin without reaction, it would seem as if an immunity against the products of the bacilli could be produced in man. Whether such individuals possess also an immunity against the bacteria themselves, and therefore are protected against reinfection, must be settled by observations extending over a longer period of time. The observation of Baudach in this connection is pertinent: "The question of the production of immunity is unsettled. If there is none produced, then the only point of difference between tuberculin 'R' and the old tuberculin is the greater toxicity of the former. The class of cases in which the use of the remedy is justifiable is very limited."

---

#### THE TREATMENT OF APOPLEXY.

In the first number of *La Médecine Moderne* for 1898 GRASSET, in speaking of the treatment of apoplexy, refers first to the usefulness of revulsion, and secondly, to the means that should be resorted to for modifying arterial tension. For this purpose he believes that venesection is useful in many cases, particularly if there is circulatory excitement and general turgescence. Revulsion is to be obtained by the use of purgatives. Repeated small doses of calomel in milk may be used, or if these are not sufficient, the following mixture may be given every quarter of an hour until the bowels are moved:

- ℞ Croton oil, 1 minim;  
Castor oil,  
Oil of sweet almonds, of each 1 ounce;  
Syrup of lemon, 2 ounces.

It may be well to aid the movement of the bowels by the use of glycerin injections, or of oil, or by the use of sulphate of sodium solutions. Counter-irritation by the way of mustard plasters to the arms and legs may be used. If albuminuria does not exist as a result of renal disease, blisters may be applied to the thighs. Should a condition of cardiac and circulatory feebleness develop, ammonium may be given or caffeine may be used. In other instances camphorated oil (ten-per-cent. strong) may be given in the dose of fifteen to thirty minims every few hours; and finally, injections of artificial serum are suggested. These, however, we should regard as dangerous. After the acute symptoms have passed by care should be taken to support the patient by the use of milk and bouillon, by the administration of bitter tonics, such as kola, and perhaps by the use of cognac or other concentrated alcoholic stimulant.

#### THE TREATMENT OF FATTY HEART.

PLIQUET in *La Presse Médicale*, No. 7, 1897, discusses the causes of fatty heart and its treatment. It comes, as he points out, in the obese and gouty and as a result of chronic poisonings, such as antimony and arsenic; it also follows the infectious diseases, such as typhoid and puerperal fever in particular. Where it occurs in the obese and is not a true fatty degeneration, the administration of thyroid gland may be of advantage; if the patient is accustomed to the gland moderate exercise is permissible. A proper diet should also, of course, be ordered for such patients. Laxatives should be freely given and diuretic waters should be administered. There should be an absolute avoidance of alcoholic liquors and of tobacco.

Pliquet believes that the efficacy of thyroidal preparations in such cases is incontestable. Where the heart has undergone fatty degeneration good results are obtained by the use of caffeine and ether, or sparteine may be given subcutaneously as follows:

- ℞ Sulphate of sparteine, 15 grains;  
Distilled water, 2 ounces.

Ten to twelve minims of this solution may be given hypodermically every two hours.

Pliquet believes that sparteine is particularly of value because of its long-sustained influence upon the heart. It may be given

by the mouth in one per cent. in the dose of twenty to thirty drops three times a day, or in pill form with a little extract of cinchona, as in the following pill:

- ℞ Extract of sparteine, 8 grains;  
Extract of cinchona, 40 grains.

Make into twenty pills and use two to four a day.

Preparations of kola and coca are also useful in some of these cases. Where there has been acute intoxication, with secondary fatty heart, sudden cardiac collapse may have to be combated by inhalations of oxygen, injections of ether, caffeine, and of camphorated oil. The use of arsenic in many cases of fatty heart also produces very good results. In all patients with fatty heart the administration of chloroform should be resorted to with the greatest possible caution, and if possible avoided.

#### THE TREATMENT OF DYSPEPSIA.

In *Revue de Thérapeutique* of January 15, 1898, we are told that ROBIN recommends the following prescription in those cases associated with pain and pyrosis:

- ℞ Hydrated magnesia, 20 grains;  
Subnitrate of bismuth, 6 grains;  
Prepared chalk, 8 grains;  
Bicarbonate of sodium, 15 grains.

These parts are made into one powder and twenty similar powders are given to the patient. One of these is taken three hours after meals. Should the painful symptoms be excessively severe one-sixtieth of a grain of hydrochlorate of morphine or one-sixth of a grain of powdered opium may be placed in each cachet. For the arrest of acetic fermentation absolute avoidance of alcoholic drinks must be insisted upon, and where lactic fermentation is marked the quantity of fruit eaten should be limited. Such cases may be benefited by the administration of fluoride of ammonium 15 grains, distilled water 10 ounces, and one or two teaspoonfuls of this solution given three times a day when the discomfort is felt. Where butyric acid fermentation is present, which is a more rare condition, Robin uses the double iodide of bismuth and cinchonidin under the name of erythrol, as follows:

- ℞ Erythrol, 1-6 to 1 grain;  
Hydrate of magnesia, 2 to 4 grains.

To be placed in a cachet and taken after meals.

In many instances two small doses of arsenic or bromide of potassium or Fowler's or Pearson's solution may be given with advantage. In those cases where the dyspepsia

depends upon hepatic congestion and cirrhosis, hydrotherapeutic measures may be resorted to and mild alkaline waters, such as those of Vichy or Carlsbad, may be taken. In other instances the waters of Homburg are advantageous. In those cases where there is cardiac disturbance along with the dyspepsia, the use of tobacco must be stopped, alcohol used in moderation, and tea and coffee taken only in small quantities. The evening meal should consist entirely of vegetable material and bread should be forbidden. In the way of medication it will be useful to apply a certain amount of friction over the precordial region, and it may be necessary where there is cardiac pain to apply the following ointment to the precordium:

- ℞ Veratrin, 2 grains;  
Extract of opium, 12 grains;  
Essence of turpentine, 30 minims;  
Essence of peppermint, 12 drops;  
Benzoated lard, 1 ounce.

A small part of this is to be rubbed into the precordium once or twice a day. In other instances a capsule of ether will exercise a favorable influence in bringing up wind. Should there be marked dyspnea along with cardiac disease, good results often follow the inhalation of oxygen. The gas should be slowly taken to the extent of five to ten quarts.

Should syncopal attacks come on, inhalations of nitrite of amyl are useful and caffeine may be administered at the same time. For allaying nervousness, valerianate of ammonium may be given or the following prescription may be used:

- ℞ Arsenite of potassium, 1½ drachms;  
Cherry laurel water, 2½ drachms;  
Ether, 1 ounce;  
Essence of valerian, 4 ounces.

S.: A dessertspoonful to a tablespoonful every two hours until the symptoms disappear.

Should the symptoms persist in spite of treatment, it will be necessary for the patient to leave his business and go to a health resort for the improvement of his general condition.

#### A PRESCRIPTION FOR TENDERNESS OF THE GUMS.

- ℞ Hydrochlorate of cocaine, 2 grains;  
Chloroform, 15 minims;  
Glycerin, 6 drachms;  
Essence of roses, 6 drops.

Apply a small quantity to the painful portion of the gum.

—*Journal de Médecine de Paris*, Jan. 23, 1898.

#### TREATMENT OF CATARRH OF THE BLADDER.

In catarrh of the bladder with pain in the posterior part of the urethra and inflammation of the prostate or epididymis, we are told by the *Journal de Médecine de Paris* of January 23, 1898, that the following prescription may be used with advantage:

- ℞ Hydrochlorate of morphine, 4 grains;  
Sulphate of atropine, 1 grain;  
Distilled water, 7 ounces.

Inject into the rectum seventy-five minims of this solution. Its good effects will be noticed in ten or fifteen minutes. If there is much fever Scharff recommends the injection into the rectum three times a day of seventy-five minims of the following solution:

- ℞ Hydrochlorate of cocaine, 15 grains;  
Antipyrin,  
Salicylate of sodium, of each 160 grains;  
Distilled water, 3¼ ounces.

#### THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM BY INTRAVENOUS INJECTIONS OF CORROSIVE SUBLIMATE.

In the *Centralblatt für die Gesamte Therapie* for January, 1898, SINGER speaks of this treatment. After admitting that the various preparations of the salicylates represent to some extent a true specific for rheumatism, and commenting upon the fact that the disease probably depends upon microbic infection, he suggests that it might be well to introduce into the blood current some antiseptic substance directly without having this substance absorbed by the intestine or skin. As the salicylates do not lend themselves readily to intravenous injections Singer has employed sublimate injections. He tried this treatment upon eleven patients in the general hospital in Vienna suffering from acute articular rheumatism. The injections were made into a vein at the elbow, constriction of the arm being made so as to produce engorgement of these veins. The injection was made after the part had been thoroughly washed and disinfected by means of a Pravaz syringe (which holds from twenty to thirty minims). The following prescription was employed:

- ℞ Corrosive sublimate,  
Chloride of sodium, of each 2 grains;  
Distilled water, 160 minims.

The needle having been inserted into the vein towards the trunk the bandage upon the upper part of the arm was removed, and

the fluid was injected very slowly indeed into the vessel; afterwards the puncture was closed by iodoform gauze. In no case did the author observe thrombosis in the vein after the injection, and he practised the method upon the two arms alternately, using from six to eight injections. The patients were not troubled with any evidences of stomatitis.

Singer asserts a remarkable diminution in the articular pains takes place, this being rapid, constant, and in proportion to the application of the remedy. Usually within half an hour of the application the effect is manifest. The febrile movement is also moderated. Four out of the eleven cases treated had cardiac trouble; out of the seven other cases three presented cardiac complications during the course of the treatment.

Singer believes that the contraindications to this treatment are general debility, the existence of renal disease, and idiosyncrasy. Symptoms of mercurialism can be controlled if the minute that they appear the treatment be stopped.

#### TREATMENT OF DYSMENORRHEA.

The following formula is given in *Les Nouveaux Remèdes* of January 24, 1898:

- ℞ Tincture of hydrastis canadensis, ¼ ounce;  
Viburnum prunifolium, ¼ ounce.  
Ten drops every two hours.

#### A PRESCRIPTION FOR VOMITING OF PREGNANCY.

- ℞ Hydrochlorate of hydrastinine, 15 grains;  
Distilled water, 3 drachms.  
Fifteen to 30 minims hypodermically.

—*Les Nouveaux Remèdes*, Jan. 24, 1898.

#### TREATMENT OF GONORRHEA.

In the *Revue Pratique Obstétrique et de Gynecologie* for January, 1898, the following formulæ are given for the treatment of this disease; the statement first being made that solutions of formalin in the proportion of 1:10,000 should be used for injection purposes four times a day. For the prevention of erections and nocturnal emissions Finger recommends:

- ℞ Camphor, 2 grains;  
Mucilage of acacia, 3 ounces;  
Two teaspoonfuls every two or three hours.

Or,

- ℞ Pure lupulin, 15 grains;  
White sugar, 30 grains.  
Divide into ten powders and take three of these a day.

Or,

- ℞ Lupulin, 15 grains;  
Hydrochlorate of morphine, 1 grain;  
White sugar, 30 grains.  
Make into ten powders and take three a day

Or again,

- ℞ Lupulin, 15 grains;  
Camphor, 2 grains;  
Extract of hops, a sufficient quantity to make ten pills, of which six should be taken a day.

Or,

- ℞ Powdered digitalis leaves, 4 grains;  
Lupulin, 15 grains.  
Make into ten powders. Take one three times a day.

Or,

- ℞ Bromide of sodium, 2 to 4 drachms;  
Camphor and lupulin, of each 8 grains.  
Make into ten powders and take one of these night and morning.

Or,

- ℞ Monobromate of camphor, ¼ drachm.  
Make into six cachets and give three or four cachets a day.

In some cases antipyrin is a useful analgesic when prescribed in the dose of ten to twenty grains, and the same may be said of the citrate of cornutine in the daily dose of one-tenth of a grain.

#### TREATMENT OF COUGH OF PHTHISIS.

The following prescription is given by the *Journal de Médecine de Paris* of January 23, 1898:

- ℞ Fluid extract of hydrastis canadensis,  
Fluid extract of ergot, of each 6 drachms.  
Four or five times a day after food, administer 30 to 40 drops of this solution in a little water.

It is asserted that hydrastis canadensis promptly checks the cough, and that the muco-purulent expectoration is markedly diminished.

#### THE USE OF RECTAL INJECTIONS OF SALT WATER IN PLACE OF INJECTIONS OF ARTIFICIAL SERUM INTO THE VEINS.

The *Journal de Médecine de Paris* tells us that PAUCHET has used salt water in the proportion of 8 per 1000 in hemorrhages after surgical operations and in parturition by means of rectal injections, with very good results.

It is well known, of course, that these injections can be given intravenously in case of great hemorrhage accompanied by shock, and that they frequently do a great deal of good. So, too, subcutaneous injections of

artificial serum are often exceedingly valuable. Pauchet claims, however, that the use of saline solution by the bowel is followed by good results and has none of the disadvantages of either intravenous or hypodermic injection. The patient receives a rectal injection of a pint of hot salt solution, and this may be repeated if the collapse is great or the hemorrhage has been great, two or three times in the course of a day. He has known of cases where as much as three quarts have been absorbed in the course of twenty-four hours. Should the bowel become intolerant then other methods have to be resorted to, but Pauchet asserts that the pulse improves, the urine becomes abundant, the mouth becomes moist, and that this treatment also seems to diminish the vomiting following the use of an anesthetic. A similar recommendation to that of Pauchet is made by Fieux in regard to post-partum hemorrhage, he also claiming that such injections are an exceedingly valuable method of treatment.

#### HYPODERMIC INJECTIONS.

The following formulæ are given by *Les Nouveaux Remèdes* of January 24, 1898, for the use of hydrobromate of quinine:

℞ Neutral hydrobromate of quinine, 15 grains;  
Distilled water, 2½ drachms.

To be given in the dose of from 15 to 60 minims.

Or,

℞ Basic hydrobromate of quinine, 15 grains;  
Antipyrin, 30 grains;  
Distilled water, 2½ grammes.

Fifteen to 45 minims at a dose.

For the treatment of uremia Bricon and Pouillet suggest:

℞ Hydrochlorate of pilocarpine, 2 grains;  
Distilled water, 2½ grammes.

Ten to 30 minims to be given hypodermically in case of uremia.

[We believe that this should be resorted to with caution.—ED.]

Crédé is credited with the use of a similar prescription for puerperal eclampsia. [This is certainly contraindicated unless the circulation is exceedingly strong.—ED.]

#### THE TREATMENT OF HEMOPHILIA BY THYROID GLAND.

DELACE has reported the case of a woman who because of hemophilia suffered from excessive anemia. The facies were exsanguinated in appearance, the mucous membranes absolutely colorless. The gums bled

easily on touch, and the extremities and body were covered with a purpuric rash. Menstruation was profuse and lasted from twelve to fourteen days. She was treated by the various hemostatics and by repeated injections of ergotin without much result. Seeing that Vigier had employed capsules of thyroid gland in the treatment of metrorrhagia, Delace concluded to try this remedy, and three capsules of thyroid gland were given each day, with the result that the loss of blood was immediately arrested. The patient gained in weight, the purpuric spots disappeared, the gums became firm, and some color began to appear in the face. Cardiac palpitation was decreased. At no time was the dose greater than three capsules a day.—*Journal de Médecine de Paris*, Jan. 23, 1898.

#### THE USE OF METHYLENE BLUE IN THE TREATMENT OF DIABETES MELLITUS.

Our attention is called to this matter by *La Médecine Moderne* of January 22, 1898. A man of fifty-three years, suffering from headache and general malaise and other evidences of diabetes mellitus, including glycosuria and albuminuria, received five to eight grains of methylene blue, and under these circumstances the albumen materially diminished and the sugar markedly decreased in quantity. The quantity of urine was also decreased. In a second case the results were equally satisfactory. In this instance four pills of methylene blue to the amount of two grains each were administered each day with marked benefit. One advantage of this treatment is that it tends to relieve any neuralgic pains from which the patient may be suffering.

#### THE TREATMENT OF POISONING BY MUSHROOMS.

*La Presse Médicale* of January 12, 1898, contains the following recommendations in regard to this treatment, it having been carried out with success a number of times.

First, half an ounce of castor oil in black coffee was given, and after this a warm rectal injection containing one pint of water, some senna, and six drachms of sulphate of sodium.

After the bowels had been thoroughly moved, a second warm injection containing one and a half pints of warm water and twenty drops of belladonna was given, and for distinct antidotal purposes full doses of

atropine in boiled distilled water were administered hypodermically.

Venesection was also resorted to to remove poisoned blood from the body and to allay arterial tension, and after this had been done intravenous injection of a pint of artificial serum was performed, the temperature of the fluid being that of the body. Gentle stimulation was resorted to and cups of hot tea and coffee and hot punch were administered.

#### THE TREATMENT OF ABORTION.

In the *Medical News* of November 6, 1898, H. J. GARRIGUES writes upon this old topic, which always possesses interest to the general practitioner. In the course of his paper he points out that the treatment may be prophylactic or curative. The former is especially called for in cases of habitual abortion, in which a history of syphilis is so frequently elicited; and by instituting specific treatment of the husband, the wife, or both, it may be possible for pregnancy to be completed. It may be necessary for the patient to change her occupation or location of residence, especially if the latter should be in a malarious district. Sometimes a uterine displacement exists which may be remedied before pregnancy occurs. If no such indications are found, the writer has sometimes succeeded in preventing abortion by having the patient remain in bed during the week corresponding to what would be a menstrual period if pregnancy had not occurred. Confinement to the bed should continue from two days before menstruation would be due under non-pregnant circumstances to five days after. At the same time a teaspoonful of fluid extract of viburnum prunifolium should be administered three times a day. During the remaining three weeks moderate exercise in the open air is indicated, and at the same time iron, quinine, red bone-marrow, arsenic and phosphorus may be given with benefit. In the author's opinion this is a better plan than forced and complete rest during the whole of pregnancy, which treatment is very weakening and may assist in the causation of abortion or make the patient less fit for the ordeal of childbirth. Coition, dancing, horse-back riding, bicycling, gymnastics, and all sorts of sports or fatiguing work must be absolutely forbidden.

If abortion threatens, as indicated by loss of blood from the uterus, it becomes necessary to decide if further prophylactic measures are advisable. Under these circumstances it is

often possible to prevent abortion by means of complete rest and the administration of viburnum prunifolium, opium suppositories, a saline, and the application of an ice-bag to the hypogastrium. If hemorrhage is considerable or has continued long, if the cervical canal is open, if the ovum is felt projecting into the vagina, abortion is inevitable, and then the sooner the uterus is emptied the better it will be for the patient.

The old treatment, consisting in vaginal injections of ice-water, tamponade, and removal of the ovum, exposes the patient to great danger, and at best leads to a tedious recovery. Garrigues rarely uses a tampon. The indications for its use are only when there is great weakness, necessitating a better general condition of the patient before having recourse to operative interference, and also when, on account of unfavorable surroundings, it is wise to remove the patient to a hospital.

In many (even new) books the use of tents for producing dilatation of the cervical canal is recommended. The writer is opposed to the employment of any kind of tent except that, if it is deemed necessary for other reasons to tampon, he uses iodoform gauze in the upper part of the vagina, and introduces a portion of the gauze into the cervical canal. If immediate dilatation is necessary it is, in his opinion, much better to use either the expanding or coniform dilators. If a tampon is used, only the portion which is placed in the upper part of the vagina should be composed of iodoform gauze. The portion of the tampon in the lower part of the vagina should be made of pledgets of absorbent cotton wrung out of a one-per-cent. creolin emulsion, and should be inserted with the aid of a Sims speculum, and so tightly packed that it effectively prevents any loss of blood.

In most cases it is the author's practise to dilate the cervical canal instrumentally. For abortion occurring during the first three months of pregnancy, all that is required for this purpose is a set of conical, hard-rubber dilators, or a dilator embodying the principle of a glove-stretcher. During the fourth and fifth months a higher degree of dilatation is required, and for this purpose he employs a set of olive-shaped hard-rubber dilators. The set consists of ten olives, ranging in circumference from 33 to 68 millimeters. At a later date of pregnancy Hank's large dilators, ranging from 73 to 137 millimeters, are very useful. When the necessary degree of dilatation has been effected, the uterine cav-

ity may be emptied. Much less violence is required in introducing dilators than in forcing a finger through a closed os, as has been recommended.

For the purpose of emptying the uterus, Thomas' small dull wire curette is useless, and may lead the operator into an erroneous belief that the cavity is empty. On the other hand, his large dull wire curette, with an opening admitting the tip of a forefinger, is an admirable instrument for the purpose of both loosening the ovum from the walls of the uterus and removing it by seizing it between the instrument and the index-finger, as well as for scraping off the decidua vera. Formidable as the instrument appears, the writer has used it many times with the greatest satisfaction. Before the end of the second month of pregnancy it is too bulky, and in such cases he employs the old Recamier curette, which also is dull, but much smaller and better adapted for this period. At a very early stage, say at the end of the first month, it is even necessary to use Simon's sharp spoon or Sims' curette. For the removal of the fetus, a blunt forceps with heart-shaped or oval rings is required, and the same instrument may, in rare cases, be necessary to assist in removing the placenta; but in nearly all cases he prefers the combined use of the finger and the large dull wire curette. By using moderate force one can safely scrape as long as anything comes away. When the uterus has been emptied and is small, it is only necessary to pack the vagina as described above. If it is larger, say corresponding to three months' gestation, it is his practise to pack the uterine cavity with iodoform gauze before tamponing the vagina. The tampon is removed the following day, and after that a vaginal douche of one-per-cent. carbolyzed water is given twice daily. The patient should remain in bed at least one week.

Immediately before and after curettage the uterine cavity should be flushed with two pints of a one-per-cent. creolin emulsion, which is both antiseptic and hemostatic. For this purpose the author uses a single current metal tube. There is no advantage in combining the curette and irrigation tube in one instrument. He prefers, on the contrary, to distinctly see what is scraped away. To use the finger as a curette is in most cases unsatisfactory, even when one hand is used for pressing the fundus down. The finger is often arrested at the internal os or does not reach the uppermost part of the cavity, and

at all events it can only be used to separate the ovum from the uterus, and cannot remove the decidua vera.

When the uterus is empty and the tampon has been applied, ergot may be administered to the best advantage, and it should be continued in doses of one teaspoonful three times daily until an ounce has been taken.

Should pain be an element, which is exceptional after the uterus is empty, there is no objection to the administration of an opiate. In most cases it is certainly advisable to employ anesthesia. It is hardly necessary to say that the rules of clean midwifery should be carefully observed.

Should pregnancy be terminated after the fifth month, and the placenta not be expelled, either by the uterine contractions or by Cr  d  's method, it is better to tampon the uterus and vagina as described before, and await further developments. If the placenta does not come away within twenty-four hours the dressing should be renewed and left in place a day longer, and then if the placenta yet remains within the uterus its mechanical removal is positively indicated. The intra-uterine use of steam has of late been recommended, but it has been found in cases in which hysterectomy has subsequently been performed that it requires four weeks before the cauterized tissue is regenerated. Experience in other conditions in which Garrigues has used steam after curettage has shown that its use is often followed by a protracted purulent discharge. Consequently, its employment does not seem advisable.

That the treatment advocated in this paper may be used even when the os is closed follows from its applicability to cases of induced abortion. The writer has had but four such cases, which were described in a paper read before the American Gynecological Society. The operation was performed at the end of the first, the second, and the fourth months, and at the end of the seventh week of pregnancy. All the patients made good recoveries within a week, and at no time were seriously ill.

Our resources are limited for the treatment of septic cases, and the prognosis should be very guarded. If the fetus, ovum, or placenta is retained, or should there be hemorrhage, the cervix must be dilated and the uterus curetted and washed out. In doubtful cases it is often better to refrain from curetting, for by this operation the protective wall which Nature throws out may be destroyed, and infectious germs given a ready

means of penetrating to the deeper tissues. Under all circumstances great attention must be paid to the general treatment in septic cases. The patient should be given as much whiskey or brandy as she can tolerate—twelve ounces or more during the twenty-four hours. Salophen given in five-grain doses every three hours has seemed beneficial. It is needless to say that the bowels should be kept open.

In localized septic cases a treatment similar to that recommended for simple abortion is indicated. In septicemia whether or not local treatment is necessary will depend upon the obtaining circumstances.

---

#### THE TREATMENT OF SCIATICA BY LOCAL APPLICATIONS.

This somewhat unusual method of treating sciatica is recommended in a Paris thesis. The treatment consists in applying by means of a compress half an ounce of pure hydrochloric acid over the course of the painful nerve, and after this a bandage is applied enveloping the part. An ointment is applied to the burn. The method is somewhat painful, and in a short time white blisters filled with serum appear, but these in turn disappear in the course of a few days. GENNATAS asserts that after the first application the patient is relieved, and that after a few days another application should be made to the spot near-by the first. In the cases Gennatas treated a cure was produced after the applications during fifteen to twenty-five days.—*Journal de Médecine de Paris*, Dec. 19, 1897.

---

#### THE TREATMENT OF TUBERCULOSIS BY CINNAMIC ACID.

HEUSSER and LANDEW have treated a large number of tuberculous patients by this means. The drug is to be given hypodermically and intramuscularly. At the beginning two minims of cinnamic acid is injected, and this is gradually increased until one gramme is given. The injection is followed by burning pain, which disappears, however, quite rapidly. The patient feels fatigued, there is congestion of the head, and sometimes an attack of vertigo. After the treatment has been continued two to four weeks the patient gains in weight, his appetite is increased, cough is diminished, and the pulmonary sounds improve. The quantity of yellow elastic fiber and the bacilli in the sputum also decrease.

As a secondary result of the treatment

tumefaction of the cellular tissue is sometimes noted. This method of treatment they tell us requires great constancy and patience on the part of the doctor and patient, and should, having once been begun, be persisted in until sufficient time has elapsed to prove it of no value. They quote Landell, who reached the following conclusions:

Cinnamic acid is a remedy which exercises considerable influence upon the progress of tuberculosis.

As the remedy is not entirely innocuous it must be used with some caution.

There is no doubt that injections of cinnamic acid distinctly ameliorate and perhaps cure pulmonary tuberculosis.—*Journal de Médecine de Paris*, Dec. 5, 1897.

---

#### THE TREATMENT OF GRIPPE.

In the *Revue de Thérapeutique Médico-Chirurgicale* of January 15, 1898, the following treatment for this disease is recommended:

Absolute and prolonged rest in bed until after all fever has disappeared and the principal symptoms have been ameliorated, notably pulmonary manifestations; an exclusive liquid diet, consisting of milk, coffee, mild stimulants, and hot drinks. The coffee is useful as a diuretic and to antagonize nervous depression. Care should be taken to maintain diuresis by this means. It is well to resort to antiseptics of the respiratory passages by gargling with some mild antiseptic gargle, and by spraying out the nose with a spray of liquid albolene with menthol in the proportion of three to six grains to the ounce. It is well to begin the treatment by a mild calomel purge. Where the symptoms are chiefly fever, great nervous depression, sore throat, hoarseness, and other manifestations of respiratory difficulty, it is believed that quinine is the specific remedy, the hydrochlorate being preferred and being given in the dose of ten to fifteen grains. Such a dose may be given three times in twenty-four hours, in cachets preferably. Should the stomach be intolerant the hydrochlorate of quinine may be given by the rectum, dissolved in the proper quantity of hot water, or suppositories of hydrochlorate of quinine may be used. Antipyrin seems to be of value in combating fever and quieting pain, but it often is a dangerous remedy in old persons. If the temperature is very high, warm baths continued for fifteen to twenty minutes are advisable. To combat the headache phenacetine com-

bined with antipyrin may be used. To overcome the evidences of congestion in the pulmonary mucous membranes, from ten to fifteen grains of chloride of ammonium and five to ten grains of Dover's powder may be given in the course of the day. To overcome cough and produce sleep, opium, morphine or codeine may be used.

[We would prefer the bromides with or without small doses of chloral in preference to opium in such cases.—ED.]

#### THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

The *Revue de Théraputique* of January 12, 1898, makes the following recommendations: For controlling the sweats give  $\frac{1}{10}$  of a grain of neutral sulphate of atropine once or twice a day, or one-third of a grain of tellurate of sodium once or twice a day. For the insomnia give injections of morphine. For the tendency to excitement or delirium use chloral and bromide of potassium. During convalescence compresses are to be applied to the articulations, for the purpose of causing the absorption of fluid, and massage, vapor baths, and the iodide of iron in syrup after each repast are to be employed. If possible a visit to hot springs is to be urged.

The treatment of the principal complications, as pericarditis, is counter-irritation or scarification over the precordium; if a failing heart is present give doses of digitalis, subcutaneous injections of ether, caffeine, sparteine, camphorated oil or alcohol or Hoffmann's anodyne. Should pericardial effusion form, paracentesis should be performed. For the treatment of myocardial trouble similar medicines may be given. The iodide of potassium in small doses is sometimes useful. Pulmonary edema is to be met by the use of counter-irritation and digitalis; pleurisy by milk diet, diuretic drinks, and salicylate of sodium. Cerebral rheumatism is to be treated by suspending the salicylate of sodium, by giving a cold douche to the head, the patient being in a hot bath. Chorea is to be combated by the use of antipyrin or arsenate of sodium.

#### THE THERAPEUTICS OF HOT DRINKS.

Chronic indigestion is sure, sooner or later, to be followed by disturbance of the motor apparatus of the digestive tract, usually affecting more particularly the stomach, which reacts less readily to stimulation. There results a condition of impaired secretion, plus

a greater or less degree of muscular atony, which must be combated at an early stage if we wish to avoid an incurable degree of gastric dilatation. Among the remedies at our disposal hot drinks have, of late years, attained considerable vogue. The ingestion of tepid fluids exerts a marked sedative action on the gastric mucous membrane and often relieves the painful sensations following meals in chronic dyspepsia. Less recognized, perhaps, is the influence of hot drinks on the motor functions of the stomach. In the ordinary course of events nothing remains in the stomach six hours after a meal, and the presence of alimentary débris after that period indicates the presence of some degree of muscular paresis. This condition of things may be greatly benefited by the use of hot water with or immediately after meals; but in chronic cases, permanent benefit can only be obtained by perseverance, the treatment being methodically carried out for some months. As might be anticipated, the hot water treatment does not ameliorate the secretory defects in the same degree as the muscular weakness, but by maintaining the stomach in a hygienic condition we may, at any rate, hope to check further degradation of the peptic glands. The temperature of hot drinks should be from 105° to 110° F., and their employment is especially indicated in cases of hyperacidity associated or not with some degree of gastric dilatation.—*Medical Press and Circular*, Dec. 29, 1897.

#### THE DANGERS AND USES OF ERYTHROL TETRANITRATE.

The *British Medical Journal* of January 1, 1898, makes the following editorial statement, which is of interest:

"We have received a detailed account of the circumstances attending a recent fatal explosion of erythrol tetranitrate. It appears that a qualified chemist was engaged in stirring together in a mortar a mixture of erythrol tetranitrate and lactose, presumably for the purpose of making tabloids. The quantity of the active drug served out to him was four ounces, and there is reason to believe that the dangerous nature of the combination was fully explained to him at the time by the chief of the department. The explosion was violent, but its effects were, fortunately, local. The jury returned a verdict of 'Accidental Death,' and passed a resolution expressing their appreciation of the facilities placed at their disposal by the firm for in-

vestigating the circumstances of the case. For much of our knowledge of the physiological action of erythrol tetranitrate and its congener, mannitol hexanitrate, we are indebted to Professor Bradbury, of Cambridge, who in the Bradshaw Lecture, delivered before the Royal College of Physicians of London in 1895, gave some account of the pharmacology of these substances, based chiefly on a series of experiments made by Mr. Marshall, M.B., in Professor Schmiedeburg's laboratory at Strasburg. Erythrol tetranitrate is solid and crystalline, and melts at a temperature of  $61^{\circ}$  C. ( $142^{\circ}$  F.). When pure it is colorless, and if kept in a dark and moderately cool place is fairly stable. If exposed to warmth, and especially sunlight, it rapidly undergoes decomposition, turning yellow and giving off nitrous fumes. Its solubility in water is slight, but it dissolves readily in alcohol and in ether. It is a vasodilator and belongs to the group of which glycerol trinitrate, known familiarly as nitroglycerin, may be regarded as the typical representative. Blood-pressure experiments show that the nitrates of erythrol and mannitol have a less marked but more prolonged action than those of glycerol and glycol. On theoretical grounds it might be supposed that the new remedies would be useful in the treatment of cardiac pain, Bright's disease, migraine, and Raynaud's disease, but, as far as we have been able to learn, there has been very little demand for them. A well known pharmacist stated that he had never dispensed a prescription containing erythrol tetranitrate, and the dispenser at a large general hospital admitted that the name was not familiar to him; yet Professor Bradbury in a letter states that he is able to speak very highly of its therapeutic properties in warding off attacks of angina pectoris. Dr. Garraway mentions the case of a gentleman who has derived immense relief from its use, and won long periods of complete immunity. Dr. Bradbury, in the lecture to which reference has been made, stated that the dose of the solid organic nitrates was a grain, but that more might be given if thought necessary. He suggested that they should be taken in the form of pills or tablets, or in alcoholic solution. There is now, unfortunately, very little doubt that these new organic nitrates cannot be handled with impunity in any form in which trituration is necessary. They, in common with many other nitrates, were known to be explosive, but that they would develop such activity by being merely gently stirred

with lactose could not have been foreseen, although Professor Bradbury in his letter expresses the opinion that mixture with some readily oxidizable substance might increase the liability to explosion."

#### THE VALUE OF DIPHTHERIA ANTI-TOXIN.

At the close of an interesting article upon diphtheria by LOUIS MARTIN in *La Médecine Moderne* of February 2, 1898, the following statistics are given:

Moizard and Perregaux record 231 cases, with a mortality of 11.7 per cent.; Sevestre and Meslay 150 cases, with a mortality of 10 per cent.; Le Breton and Magdeleine 258 cases, with a mortality of 12 per cent.; Sevestre had also collected, in 1895, 1140 cases with a mortality of 18.35 per cent., and in 1896, 853 cases with a mortality of 16.24 per cent. In 1897 Barbier recorded 260 cases with a mortality of 6.28 per cent. It is evident, therefore, that abroad as well as in this country antidiphtheritic serum gives very advantageous results.

#### LUMBAR PUNCTURE.

V. RANKE (*Münchener Medicinische Wochenschrift*, Sept. 21, 1897) discusses the value of lumbar puncture in tuberculous meningitis. He has employed it in twenty-five cases, including nineteen of this form of meningitis. The author observes that in no case as yet has the puncture produced a cure. In Freyham's atypical case the recovery could not be shown to be due to the puncture. A fatal result occurred in all the author's nineteen cases of tuberculous meningitis. V. Ranke gives instances in which a temporary improvement followed upon the puncture, but in most cases there was no change in the condition of the patient. It would appear that such improvement is only seen in the early stages of the disease, when the pressure has not lasted long. The author has never seen any improvement in the optic neuritis. It must be remembered that the symptoms of tuberculous meningitis are liable to great variation. As a rule the diagnosis of this disease is easy, but in some few cases it may be impossible, and it is in these cases that a positive result obtained by spinal puncture may be of diagnostic value. As with many other observers, the author found the number of tubercle bacilli present in the fluid to be small in numbers. He concludes that lum-

bar puncture can only be of very limited diagnostic value in tuberculous meningitis. The differential diagnosis between it and the meningitis consecutive to ear disease has not always been made easy by spinal puncture. In tuberculous meningitis the fluid drawn off is clear, usually colorless, but it may be very slightly green or yellow. The specific gravity was about 1010, and the amount of albumen 1 to 1.5 pro mille. Traces of sugar were present. The amount of fluid drawn off was usually from 20 cubic centimeters to 30 cubic centimeters, and the pressure high, amounting to 160 millimeters to 300 millimeters water. In the author's cases no harm of any kind was produced by the puncture.—*British Medical Journal*, Jan. 1, 1898.

#### THE RELIEF OF OCULAR PAIN.

To resort to morphine for the relief of suffering in affections of the eye which are characterized by severe pain before the simpler and oftentimes more efficacious remedies are tried is an unwise procedure. Morphine should be the last resort, both for the reason that to subdue severe pain in a single organ more of the drug is required than is efficient in cases of more general character, and the fact that frequently its administration does not relieve the patient until its unpleasant effects overbalance its benefits and one form of suffering is substituted for another.

The simplest is often the best, and in hot water we possess an agent peculiarly potent. In the pain of iritis, traumatism of the cornea and ulcerative keratitis no other one agent will give so uniformly good results, yet to gain good results one must know the best method of application. Hot fomentations to the eye must not be poultices—save in a few conditions they are absolutely contraindicated—but should be used in one of two ways. A cotton sponge may be dipped in water that is as hot as can possibly be borne—and that is usually hotter than the patient thinks he can bear—quickly pressed and applied to the organ. It should not be allowed to remain more than half a minute, when the procedure should be repeated and continued for five or ten minutes. After an interval which is usually of comparative ease this may be repeated.

Another method is to fill a fountain syringe with water at a temperature of 115° to 130° F., and attaching to the conducting tube the glass of an ordinary medicine dropper, allow the water to flow from a height of two feet

directly upon the eyeball, collecting it in a cup pressed tightly against the lower lid. Smearing the lids with vaselin will prevent them from suffering by contact with the hot water, and with the patient in a recumbent position and with the face turned toward the afflicted side this procedure is easy of application.

Poultices, save in abscess of the lid, suppurating chalazion and hordeolum, should not be used.

Sometimes ice-cold compresses will relieve the pain quicker than hot applications, and there is no criterion but actual trial by which to decide which is the better remedy in an individual case. Ice compresses should be of one thickness of thin linen cloth torn into small squares and taken directly from a lump of ice and applied to the eye. The heat abstracted will change the cold to moist heat in a very few moments, and they should be changed even more frequently than when hot applications are used.

The abstraction of blood by means of leeches, or better the artificial leech, will be found to relieve the pain of acute inflammatory conditions with distended vessels, and may be repeated as often as required; but the relief obtained is transitory, and experience proves that the effect of repeated cuppings is apt to diminish with their frequency.

Where there is no secretion which can avert a deleterious influence by contact with the delicate structure of the eye, a pressure bandage, deftly and uniformly applied, is at times grateful, and the effect of position should not be overlooked. Pain in an eye is usually worse when the patient is in a recumbent position and when the affected eye is buried deeply in the pillows.

Pain, neuralgic in character and not associated with inflammatory conditions, is sometimes relieved by mild counter-irritation, and a mixture such as the following will frequently prove beneficial:

℞ Menthol, grs. xxx;  
Spts. rosmarin.,  
Spts. lavandul.,  
Spts. vin. gal., aa 3 j.  
Ft. lotio.

Sig.: Bathe the forehead and temples with brisk rubbing.

Of the medicines which may be dropped into the eye, the solutions of cocaine or eucaine are the most reliable. The indiscriminate use of either is, however, not to be commended, and in corneal affections the action of cocaine upon the epithelial layers

and the consequent impaired nutrition is at times absolutely injurious. Of drugs, aside from morphine we have our choice of the numerous coal-tar derivatives, which are at times very useful; but the depressant effect is quite as marked as when used for other reasons, and their contraindications should be carefully noted. Of them all, lactophenin is probably the safest and is quite as efficient as any. In ten- to fifteen-grain doses the pain of an iritis is sometimes relieved for hours, at any rate long enough to allow the patient to get needed sleep. In glaucoma secondary to a dislocated lens where all the effect of an iridectomy had been produced by the injury itself, this drug was the only one save morphine which gave relief. The pain of herpes zoster ophthalmicus, which is so persistent and severe, was also relieved in great measure by this drug in one case where morphine failed to produce any alleviation of the suffering.

In ocular pain, then, try the simpler remedies first and resort to local and internal medication only when they prove inefficient. — *The Philadelphia Polyclinic*, December, 1897.

#### SOME CLINICAL AND STATISTICAL EVIDENCE OF THE VALUE OF THE ANTITOXIN TREATMENT OF DIPHThERIA.

Dr. E. P. MANBY reaches the following conclusions in the *Liverpool Medico-Chirurgical Review* for January, 1898:

The clinical effects of the treatment are:

1. An improvement in the general condition and aspect of the patient.
2. An improvement in the local condition: (a) Diminished glandular and faucial swelling. (b) Extension of membrane ceases. (c) Earlier separation of membrane; this has been proved by actual records kept before and since antitoxin was used. (d) Diminution, and soon complete cessation, of the foul rhinorrhoea.
3. A similar improvement in laryngeal cases, evidenced by diminution in difficulty of breathing, and by actual recovery in many cases without operation, which would previously have required it. Moreover, a marked improvement in the course towards recovery of operation cases.
4. A prolongation of life in cases which terminate fatally—one and a half to three days.
5. No definite effect on pulse or temperature.

Statistical results, in the words of the Antitoxin Report:

1. A great reduction in the mortality of cases brought under treatment in the first three days of illness.
2. The lowering of the combined general mortality to a point previously not attainable.
3. The still more remarkable reduction in the mortality of the laryngeal cases.
4. The uniform improvement in the results of tracheotomy.

In fact, "a remedy of much greater value in the treatment of diphtheria than any other yet introduced."

#### THE TREATMENT OF UREMIC VOMITING.

In the *Journal des Praticiens* of December 25, 1897, HUCHARD recommends that in the treatment of vomiting due to gastric disturbance or uremia, lavage be resorted to for the purpose of removing the poison from the stomach, arresting the vomiting and permitting the administration of proper medications, amongst others stimulants if they are needed.

#### THE INUNCTION OF MERCURY IN TERTIARY SYPHILIS OF THE NOSE AND THROAT.

ST. CLAIR THOMSON, one time London correspondent of the *GAZETTE*, has contributed a very practical paper on this topic to the *Laryngoscope* for January, 1898. He thinks that syphilis of the upper air-passages is, in the majority of instances, a severe disease, and in its treatment we must, in the words of Tissier, "*frapper vite et fort.*" The author is accustomed to give iodide of potassium in all cases, and in the following combination:

℞ Potassii iodidi, grs. v;  
Spts. ammon. aromat. ℥ xv;  
Tinct. gentian co., q. s. ad f 3 ij.

Ft. dosis.

This is given, well diluted, three times a day, and, if taken before meals, the writer finds it agrees well and appears to be more effectual than even larger doses given after food. If for any reason inunctions of mercury are not ordered, or even in addition to the inunctions in severe cases, the writer adds to the above a drachm of liquor hydrargyri perchloridi.

While in many cases this rapidly relieves the symptoms, as remarked, it is on the administration of mercury by the skin that most reliance is to be placed. The only serious

objection to this method of administration is the possible state of the patient's gums. Teeth which are carious, or coated with tartar, need not offer any difficulty, for they can be quickly scaled and filled; but if the gums are chronically inflamed, the inunction must be given with the greatest circumspection, for it is in this form that mercury is most apt to cause severe stomatitis. If the gums are ordinarily healthy and the teeth in good condition, the writer has not seen the least trouble arise in the mouth from thirty, or even forty, consecutive rubbings of a drachm of blue ointment nightly. The prescription is ordered as follows: Six drachms of unguentum hydrargyri are ordered to be dispensed in six separate packets of oiled paper. The patient takes a warm bath in the evening, and, if not accustomed to free ablutions, is recommended to scrub himself liberally with soap. Then, sitting in front of a fire, if it is winter-time, one of the packets is opened and the drachm of ointment is patted on a part of the body in about twelve or more little dabs. With the palm of his hand the patient then steadily—not roughly—rubs the ointment until it has practically all disappeared, as it will do, leaving only a dirty stain. He is advised to take time over this, devoting at least a quarter of an hour to it. He then puts on an old suit of flannel pajamas and goes to bed. If he belongs to the class of life which can command the time and opportunity for daily warm baths, he is recommended to take one in the morning, afterwards dusting with finely powdered boracic acid the region anointed on the previous evening. On the second evening another region is selected and another drachm of ointment is used. As a routine the patient is directed to select a different region for each of the six packets; these regions are: the inside of the two thighs, the sides of the body from the ribs to the iliac crests, and the flexor surfaces of the arms. If the patient belongs to the working class, he takes a weekly warm bath on the seventh evening, and on that night no inunction. There is no therapeutic reason whatever in omitting the inunction once a week; but it gives the patient a fixed order of procedure, and an even number of regions for the inunctions. Also by ordering only enough ointment for six applications, we can insure a freshly prepared supply once a week. This is an important point in helping to avoid irritation of the skin. Berkeley Hill recommended that the ointment be made up with lanolin, and that a drachm of olive

oil be added to each ounce of it. The effects must, at first, be constantly supervised.

The writer has never found any necessity to interfere with the patient's diet as long as it is wholesome and nourishing. He should avoid drinking spirits, and be as abstemious as possible in the consumption of alcohol generally; and if the mouth is affected, he should give up smoking. The great necessity of attention to the mouth and teeth is strongly impressed upon him; hence he is urgently recommended to brush his teeth thoroughly, at least morning and evening, and to rinse his mouth after every meal with a chlorate of potash or some antiseptic mouthwash. The following is the gargle which is usually prescribed at Aix-la-Chapelle:

- ℞ Liq. alum. acet., 100.00;  
Aq. floris aurantii, 300.00;  
Aq. destill., 800.00.

Although patients are generally recommended to avoid fatigue and undue exposure, especially after perspiration, as a rule they continue their ordinary avocations. The writer has had military officers who continued the inunction when camping out under canvas, and who performed their duties and declared that they felt better than they had done for months.

This brings us to one of the chief objections to this form of treatment, viz., that it is out of the question if the disease is to be kept secret. Certainly in the case of married men who have not confided in their wives, this objection is a serious one, and forms one of the reasons for preferring to have the treatment carried out at Aachen (Aix-la-Chapelle), Arkansas, or other sulphur springs. Still the author has known patients, like the officers above quoted, who succeeded in carrying out the treatment under what would have appeared the most adverse social conditions. The objection may be met to some extent by having the inunction carried out by a professional *frotteur* at some public baths. If the rubbing is not carried out with the patient's own hand, it may be well to remark that whoever undertakes the task should have the hand protected with a rubber glove, otherwise he may suffer from mercurialism.

The duration of the treatment varies, of course, with the extent and progress of the disease and the condition of the patient. Roughly speaking, twenty-five to thirty and even forty inunctions are required. The amount at each inunction will vary, according to the case, from twenty to sixty grains

(one to five grammes). With the disappearance of the symptoms the chronic intermittent treatment must be prosecuted, for it is necessary not only to treat patent syphilis, but also latent syphilis. For reasons already stated, this applies particularly in the tertiary manifestations of the nose and the throat. This chronic treatment will again vary according to the amount of previous treatment, the obstinacy of the affection, the condition of the patient, etc. As a rule, he gives no mercurial treatment for six months; at the expiration of that time the patient is advised to have some fifteen rubbings. At the end of another six months a second fifteen rubbings, and a third rubbing half a year later. If there has been no reappearance of any symptoms during these eighteen months, the patient is simply put on his guard for the future as to observing any recurrence which might arise, and advised, on their appearance, to report himself. But if from the beginning of treatment the symptoms are very obstinate, or very ready to reappear, then, between one six-months' treatment and the next, the action of mercury is kept up by the administration by the mouth of a grain of pulvis hydrargyrum cum creta in a pill, two, three or more times a day. The iodides are also prescribed as indicated.

Doubtless, the other method of introducing mercury through the unbroken skin would be equally, if not more, effectual. The writer has had no personal experience of it, but it has long been practised by Mr. Henry Lee, and has lately been advocated by Dr. Shaw-Mackenzie. The local disadvantages of hypodermic injections, and the lamentations of patients who have gone through the treatment, have prevented him from trying it. But in cases where the most rapid action is desirable—as in acute syphilitic edema of the larynx—it would, no doubt, be the method to be selected. Other writers have shown how, in such cases, a threatened tracheotomy may often be avoided.

Local treatment must not, of course, be omitted. Indeed, local treatment is of the highest importance in specific affections of this region, and in a large number of cases it would prevent the deplorable results we are too apt to see. It should not be too energetic. It consists in cleanliness and antiseptics; the local use of mercurial lotions; the judicious use of escharotics, such as the acid nitrate of mercury in the strength of 1 to 8, as recommended by Ohmann-Dumesnil; and then such surgical measures as the curette

and the knife. When the larynx is affected we are sometimes prevented from applying medicaments directly to it, owing to the tongue being painfully affected at the same time. In such cases excellent results may be obtained by a spray of perchloride of mercury (1 in 2000), or by the inhalation of the fumes of calomel from a vaporizer. It is of great importance, but the thorough constitutional treatment is even greater.

#### THE OPERATIVE SURGERY OF GASTRIC ULCER.

HEYDENREICH (*Semaine Médicale*, Feb. 2, 1898) gives the indications for surgical interference in ulcer:

1. In perforation it is absolutely necessary as early as possible before the perforation, and to wash out the abdomen. Since 1894 the mortality after operation has fallen to 52.94 per cent., and without operation the condition is almost necessarily fatal.

2. For stricture of the pylorus. In this condition it is hard to distinguish obstruction from swelling of the tissues around the ulcer, or from pyloric spasm from true fibrous stricture. For the latter there are three possible operations: (a) Resection of the pylorus; (b) gastro-enterostomy; (c) pyloroplasty. Of these the first is the most dangerous, and has no advantages over the others, unless the ulcer can be excised with the pylorus. Pyloroplasty is not applicable if the ulcer extends to the pylorus, or where the pylorus is adherent, and its walls have lost their softness. When there is a choice between the second and third methods, Mikulicz prefers pyloroplasty.

3. Operation may be required for adhesions or abscesses in connection with the ulcer. These are mostly very hard to diagnose, but it must be remembered that in some cases of persistent pain exploratory laparotomy is justified.

4. For hematemesis. Since sudden death is the exception, and many cases recover with medical treatment, the propriety of operation is still doubtful. Hartmann's twelve cases gave eight deaths and four recoveries. The author believes the chief point to be the quantity of blood lost. For violent hemorrhage laparotomy has almost always failed. Sometimes the infiltration of the surrounding tissues has rendered excision of the ulcer or ligaturing the bleeding vessel impossible. Often the bleeding comes from a branch of the splenic artery, whose territory is very dif-

ficult to reach, and sometimes the ulcer has been too small to be found. For slighter hemorrhages which become dangerous through repetition, operation may be successful; usually pyloroplasty or more often gastro-enterostomy has been performed in such cases with a view to procure rest of the stomach, and consequently of the ulcer and its healing.

5. This last consideration has led some to propose gastro-enterostomy for cases of uncomplicated gastric ulcer. The general death-rate for all cases of gastric ulcer is twenty-five to thirty per cent., for gastro-enterostomy only 16.2 per cent., and therefore the operation has less danger than the disease. Another advantage of not waiting for complications is that the patient is in better health. At any rate cases that do not improve with medical treatment in a reasonable time should be treated surgically.—*British Medical Journal*, March 26, 1898.

#### TUBERCULOSIS OF THE FEMALE GENITALIA.

T. E. MCARDLE (*American Journal of Surgery and Gynecology*, April, 1898) states that when a patient presents herself with local irritation which she has observed in the form of a slightly hardened mass, sometimes described like that of a split pea, located about the vulva, found at some point about the anterior or posterior fourchette at the opening of the vaginal outlet, or within the walls of the vagina, perhaps seen as a distant grayish-looking ulcer about the lacerated cervix, an elongated posterior lip of inflammatory tissue, with possibly a profuse leucorrheal discharge in many instances not irritating, yet so great in amount as to be distressing, perhaps now and then tinged with blood, we should not delay in looking for tubercle bacilli. When a serous bloody discharge is persistent, we should carefully consider the element of malignancy, especially if the odor is very pronounced.

Whenever the labia become the seat of local tuberculosis, the moisture and warmth of the parts favor early necrosis, but the odor is believed to be less unpleasant. The edges of the resulting ulcer are thin, purple, undermined; the base irregular, secreting a scanty, thin, puriform discharge. One point is at times healed, while the ulcer is spreading in another direction. Extension and destruction of tissues vary greatly. There may occur hemorrhage from erosion of blood-

vessels. It is apt to occur more frequently in young people, accompanied by tuberculosis of other parts of the body, and will recur at times after apparent healing. "Differentiation is not always easy as between epitheliomatous, tubercular and syphilitic ulceration, but may usually be based upon the following points: (1) Age of patient; tuberculosis is more frequent in early life and epithelioma in late life. (2) The history; antecedent syphilis; tuberculosis in other parts of the body. (3) Appearance of ulcer; more abundant fetid secretions from epithelioma. (4) Effect of treatment. (5) Bacteriological tests." When we are to exclude all the external parts, and we find that the disease is confined to the cervix, we must remember that the error has not infrequently been made of vaginal extirpation being performed for what was supposed to be carcinoma, but which in reality proved to be tuberculosis; therefore it is our duty in all cases in which there may be the least possibility of a doubt as to its being one of carcinoma or of tuberculosis to make microscopical examinations as early as possible.

Of treatment we may well say: It is the cases of local ulceration that present about the vulva, the walls of the vagina and on the cervix that the most gratifying results follow from the careful, thorough use of ichthyol, iodine, aristol; and careful curetting, complete extirpation of inflammatory areas of implicated tissue, the removal of diseased glands, repair of the lacerated cervix, the free lancing and leeching of vesicles that may present at different points, and packing with iodoform gauze. In all cases of tubercular endometritis thorough curetting should be employed. The wiping out of the cavity of the uterus with carbolic acid, the use of the peroxide of hydrogen and careful packing by means of strips of iodoform gauze should be tried exhaustively. If there should be a recurrence of the trouble, removal of the organ is advised.

Now, if we bear in mind that tuberculosis of the body of the uterus is so frequently associated with the same disease in the tubes and ovaries, it seemed to the author that, having once ascertained, without the shadow of a doubt, the existence of tubercular disease in the uterus, it is our duty to look for a similar condition of affairs in the tubes and ovaries; and while we may not achieve the same exactness of diagnosis in regard to these organs, yet if we can be morally certain of their diseased condition, it behooves

us to waste no valuable time in curetting the uterus and treating it with iodoform, but to proceed at once to the performance of an abdominal section for the removal of the uterus, tubes, and ovaries. This heroic method of treatment is advocated in primary disease of these organs. In a case complicated by tubercular peritonitis there would be no special danger in removal of the tubes and ovaries, and the operation might be of benefit to the general peritonitis, as numerous cases are on record where simple exploratory laparotomy has cured tubercular peritonitis. Later the uterus could be curetted and cauterized. If, however, the patient be also affected with phthisis, the surgeon may well hesitate about operating. If the pulmonary tubercular disease be far advanced, it is not proper to subject the patient to the risk of an abdominal section. But in the earlier stages of phthisis, if the general condition be fair, operation is justifiable, provided the patient can subsequently be placed in the very best hygienic and climatic environment.

One thought as to prophylaxis. Here, as elsewhere, prevention is better than cure. Careful study of the male genitalia has made plain the fact that tubercular disease is not uncommon in those organs; and men so diseased should be cautioned as to the danger of establishing or maintaining marital relations.

#### *THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITRE.*

ANZILOTTI (*La Clin. Mod.*, An. 4, n. 7) draws attention to the successful results obtained by surgical interference with the cervical sympathetic in the treatment of exophthalmic goitre. Unilateral, or better still bilateral, excision of the superior or middle cervical ganglion with the intervening cord brought about notable improvement in fourteen cases. Diminution of the exophthalmus, goitre, and tachycardia, and in many cases true cure, occurred after this procedure. No trophic disturbance followed, nor organic alteration in the integrity and power of accommodation. Myosis was the most constant after-effect; congestion of the face, lachrymation, and hypersecretion of nasal mucus was also observed. When no result follows the operation it is probably owing to some abnormal anatomical distribution of the cervical sympathetic. On the theory that exophthalmic goitre is due to some poison in the thyroid circulation, it is difficult to explain

why the vasomotor disturbances should be localized to the upper part of the body alone.—*British Medical Journal*, March 26, 1898.

#### *A CASE OF SUBGLOTTIC STENOSIS FROM SYPHILITIC GUMMA.*

In weighing the relative merits of tracheotomy and intubation in these cases, Dr. DAMIENO (*Archiv. Ital. di Laryng.*, No. 3, 1897) offers the following deductions:

1. Except in rare instances, intubation should always be preferred to tracheotomy in all cases of acute stenoses, and especially in children of all ages.

2. Intubation may be substituted for tracheotomy in acute and chronic stenoses of adults, especially when it does not refer to an incurable affection. It is only necessary that the passage of the tube may be effected, and that it will remain in position with a reasonable amount of certainty.

3. Intubation is the best method of permitting the removal of the cannula in tracheotomized patients, after the passage has been enlarged by the ordinary catheters or the sounds of Schrötter.—*The Laryngoscope*, vol. iv, No. 4.

#### *MINIATURE HAMMERS AND THE SUTURE OF THE BILE-DUCTS.*

W. S. HALSTED (*Bulletin of the Johns Hopkins Hospital*, April, 1898) holds that the surgery of the common bile-duct is still in its infancy. "Suture of the thickened duct is difficult enough, and suture of the normal duct out of the question," says one. "It is not worth while to exercise such great care in sewing up a slit in the common bile-duct, for it is almost impossible to prevent leakage, and a little additional leakage can do no harm if one drains," says another. "Wait until the common bile-duct dilates and thickens before venturing to open it," say all surgeons.

To close an incision in the normal ductus communis choledochus has been considered so impracticable, not to say impossible, and the result of the suture, so far as the suture itself is concerned, even of the abnormally thickened duct, so uncertain, that it is the practise of all surgeons to wait weeks or months or even years for the duct to dilate and thicken rather than interfere promptly in cases of obstruction of the common bile-duct by stone.

It is perhaps justifiable to "give Nature a chance" to expel the stone, but the operation

should never be postponed solely for the sake of giving the duct time to get thicker. The author knew from operations upon dogs and man that the normal bile-ducts can be sutured easily, accurately, almost infallibly, and without danger of leakage and constriction.

We are all more or less acquainted with the more evident dangers of postponing choledochotomy when it is indicated; the deep jaundice, the retarded blood coagulation, and the consequent danger from hemorrhage, whether an operation is performed or not; the cirrhotic hypertrophy of the liver and the concomitant hemorrhages into stomach and intestines; the acute or chronic inflammation of the bile passages; toxemia, cholemic or infectious; and the interference with metabolism, more serious, perhaps, in its remoter consequences than we have estimated. And when at last the operation is resorted to the patient is perhaps so weak that the surgeon might well wish that he had interfered earlier.

The duct lies in a deep hole, at a great distance from the surface, and it is covered by the liver, which is usually enlarged in the cases which we are considering, and which, if very large or very small, may embarrass the operator exceedingly. The suggestion of Dr. Fred. Lange to cut through one or two ribs and the diaphragm when the liver is very large we have found invaluable. And not only when the liver is large have we profited by this hint; for once when it was small and high up under the ribs, the duct, carried up with it, was perhaps even less accessible than in the cases complicated with large liver.

Once, then, because of a small liver, and several times because the livers were large, has the author divided ribs and diaphragm, and each time with gratifying results. When operating upon the bile passages of dogs he divides two or three ribs and the underlying diaphragm as a matter of routine. Cutting through a few ribs and the diaphragm on the left side enabled him to remove a large and very adherent tubercular kidney.

With the little hammers which he describes, or with a similar contrivance, he has five times sutured the common bile-duct in dogs, and twice the common duct and once the cystic duct in the human subject.

The little hammers answer the purpose better than the rods. Within the past three weeks he has twice used the hammers on human subjects. If properly employed they convert one of the most difficult operations

in surgery into quite a simple one. The hammers are of sizes to meet all cases, from the normal duct in a dog to a much dilated human duct.

It is not necessary to dissect the duct from its bed, but the wall of the duct should be clearly exposed at the site selected for the incision. The author usually incises the common bile-duct near its duodenal end because the diverticulum of Vater can be more thoroughly explored through an incision at this end of the duct, and because it is easier to suture this end than the other cystic end of the duct.

Before incising the duct, two presection stitches, to serve as retractors, should be taken. These stitches, which are subsequently removed, should enter the lumen of the duct. They are placed close together, and the incision into the lumen of the duct is carried between them.

The stone having been removed and the gall passages thoroughly searched with probe and fingers, the retractor threads are drawn apart and a hammer of the proper size introduced. The duct is then gently raised from its bed and drawn towards the operator by the hammer, the head of which is of course longer than the incision. Mattress stitches are then applied—one over the heel behind the handle of the hammer, and the others in front of the very delicate handle.

Although the finest possible needles and silk are used, the stitches necessarily perforate the wall of the normal duct. No harm results from this perforation, however, for the normal duct practically always, and the thickened duct usually, is sterile, and the stitches very soon cut their way out of the lumen and out of the wall of the duct and lie free in the adventitious tissues.

The silk which Halsted uses is very fine, and the needles, made by Wulffing-Luer of Paris, have a split eye and are almost as fine as the silk itself. One should have a needle-holder especially made and reserved for these needles. If such a needle-holder is used for coarser work it will soon be ruined.

The author has been asked why the handle was not placed in the middle of the hammer. It is placed as near one end as practicable, to enable the operator to introduce the hammer through as small an incision as possible, an incision not longer than about half the circumference of the hammer.

The advantages of the hammer are:

1. The duct to be sutured can be drawn towards the incision in the anterior abdom-

inal wall and within easy reach of the operator; it can also be manipulated nicely by the hammer.

2. The duct, whether normal or thickened and dilated, is greatly expanded by the hammer; hence the stitches can be taken with great accuracy and without fear of including the opposite wall or of occluding the lumen of the duct.

3. The operation is a very clean one, because the hammer blocks the duct, and this prevents the escape of its contents and the contents of the gall-bladder.

4. With the hammer, wounds of thin normal ducts can be easily and almost infallibly sutured, and hence the surgeon may, if he chooses, fearlessly operate upon the common duct as soon as the obstruction takes place.

The sewing of the thickened and dilated ducts is also greatly facilitated by the employment of the hammer.

#### *SOME POST-OPERATIVE LESIONS AND SEQUELÆ.*

JOSEPH PRICE (*American Journal of Surgery and Gynecology*, March, 1898) says it must have come to the notice of many operators that there are numbers of useless, often harmful, operations. It seems a common affair for surgeons (or those passing as such) to work some little end at the expense of all the risk of the regular operation, which should be done. They have only in view some temporary or peculiar benefit, without sufficient consideration of the subsequent work necessary to complete the cure. Our great natural aid lies in the recuperative abilities of the patient; but what can one expect when her vital powers are taxed for recovery from numerous ill judged operations? It is surely a matter for considerable caution. The excuses are few for repeated operations.

We will view repeated operations from two standpoints: One is where pathological conditions and the broken-down condition of the patient are such as to render a complete operation of extreme peril to the patient. To determine this question—the extent to which procedure is safe—is one of the most serious that appeals to surgical judgment. It is only such conditions that justify leaving anything for a second operation. The other and more frequent reason for reoperation—the one least to be justified, the one which is a reproach upon our surgery—is the attempted work of ignorance or that which cowardice leaves uncompleted.

Statistics have now become too much a matter of mere advertising concern, and are therefore of little value. All of us are concerned in our mortality, all want their patients to recover; but mere recovery from an operation does not in many instances mean a cure—the terms are not synonymous. Indeed, the condition of the patient, after so-called “recovery” from certain operations, is worse, the suffering greater, and life in greater peril than before.

Mere experiment is also responsible for very many repeated operations. This experimenting is not limited to the young—those fresh from our college benches. Experience convinces the author that many of our young men are more conscientious than some of their seniors. The former push their special work until they have a fitness for it. This they can afford to do, for when they begin they will know how, and therein lies the secret we are all seeking.

In every case there should be a reasonable certainty as to existing trouble, otherwise it is impossible to determine upon the method of treatment. But the error is not always of diagnosis; the operator may be moved by the craze to operate.

The subjects of these unjustifiable operations—operations for slight or undefined troubles—receiving no relief, will permit a real trouble to grow until conditions become such that relief by the most skilful surgery is difficult and of uncertain result. In many of the cases of repeated operations, the primary operation was unjustifiable; there was error of diagnosis; doubt and speculation in the mind of the operator, as to existing trouble. The primary operation may create conditions, set up adhesions, which make the second operation difficult and dangerous. All forms of exploratory operations imply ignorance and doubt, and are responsible for much of the work that has to be repeated. It is true that there are cases where an exploratory procedure serves a good purpose, and, when done under proper surgical methods and with absolute cleanliness, involves no great risk to the patient. It should be kept in mind that all surgical procedures involve more or less risk.

The tolerance of the peritoneum has tempted to a great deal of surgical nonsense, often to a carelessness or rashness which sets up pathological conditions requiring radical surgery for their correction. The author names a few of the procedures which give us a large percentage of second

operations: (1) Dilatation and curettement; (2) vaginal puncture; (3) vaginal hysterectomy. Then comes the operation that cures—abdominal section, the freeing of omentum and bowels both large and small, the removal of pathological conditions, irrigation and drainage.
